Directionally solidified eutectic (DSE) ceramic composites are investigated for potential improvement of mechanical properties over the monolithic end members. In this research, boron carbide (B₄C) - titanium diboride (TiB₂) eutectic composites are being researched for use in armor and tribological applications due to their high hardness. The microstructure of B₄C-TiB₂ eutectics consists of a B₄C matrix with TiB₂ forming a lamellar second phase, as shown in figure 1a. As the solidification rate of the materials is increased, the interlamellar spacing decreases and the Vickers indentation hardness is found to increase to ~32G Pa, though traditional Hall-Petch behavior is not observed.[1] In this research quantitative 3-D microstructural analysis is conducted by focused ion beam (FIB) serial sectioning and SEM analysis, and indentation-induced deformation mechanisms are studied by transmission electron microscopy (TEM) analysis.

TEM of B₄C-TiB₂ is performed on indented material prepared via site-specific FIB liftout to directly investigate the deformation mechanisms. Fracture events are found to occur throughout the B₄C matrix, often at the ends of TiB₂ lamellae. Additionally, while as-processed eutectics display a nearly continuous single-crystal B₄C matrix, the indented material shows a transition to polycrystalline material, as indicated in figure 1a (pristine) and 1b (deformed). Indentation and scratch studies of B₄C have shown similar behavior, specifically a transition from single crystal to a combination of nanocrystalline and amorphous boron carbide.[2] Preliminary studies of the B₄C-TiB₂ eutectic indicate that materials with smaller interlamellar spacing (and hence higher interface density) tend to suppress the structural transformation in B₄C. Amorphous B₄C exhibits a π* shoulder on the C-K energy loss peak,[2] so electron energy loss spectroscopy (EELS) is utilized to identify the spatial distribution of amorphization in deformed eutectic materials.

To understand the observed microcracking in the deformed materials, it is important to model the residual stress distributions in the composite that arise from differences in thermal expansion coefficients in the two phases. These thermal residual stresses can be very large in ceramic eutectics, on the order of a GPa in some cases [3] For the current study, 3D models of the B₄C-TiB₂ eutectic microstructure (figure 2a) were reconstructed from FIB serial sectioning data (utilizing MATLAB and COMSOL software) to serve as the basis for finite element modeling of the thermal residual stress distribution throughout the microstructure (figure 2b). The finite element models show that tensile stresses are present in the B₄C matrix between TiB₂ lamellae; these results directly correlate with the fracture behavior observed by TEM (figure 2c).
