resuscitation (CPR) model, cardiac arrest of 15 minutes was followed by reperfusion with closed chest cardiopulmonary bypass (CPB). Group 1 (n = 5) received mild hypothermia (33–34°C), Group 2 (n = 5) received deep hypothermia (26–37°C), and the levels of SOD, MDA, NO in plasma and tissues were measured during CPR.

**Results:** After cardiac arrest of 15 minutes, the concentrations of SOD in plasma of Group 1 (2615.8 ±1.6u/ml) was significantly higher than during the pre-arrest period (2586.4 ±1.78u/ml) (p <0.05), and for Group 2 (2690.5 ±35.50u/ml) also was higher than during the pre-arrest period. The concentration of SOD in plasma at 1 hour of CPB, were lower than pre-arrest (p <0.05) and nearly pre-arrest (p >0.05) at 3 hours of CPB. The levels of MDA and NO were lower than pre-arrest level after cardiac arrest of 15 minutes, at 1 hour, and 3 hours of CPB. There was no difference between the two groups. After 3 hours CPB, the concentrations of SOD in the cerebral tissues in Group 2 (1075.6 ±11.15u/mi) was significantly higher than in Group 1 (1057.2 ±11.80u/mi) (p <0.05). In the pulmonary tissues, the concentration of SOD in Group 2 (690.6 ±8.7u/mi) also was significantly higher than in Group 1 (626.67 ±23.50u/mi) (p <0.01), and the levels of MDA (4.72 ±1.5u/mi) was lower than in Group 1 (7.32 ±1.54mmol/g) (p <0.05). In the cardiac tissues, the levels of MDA and NO in Group 1 were significantly lower than in Group 2 (p <0.05).

**Conclusions:** In resuscitations using closed-chest hypothermia, CPB may decrease free-radical-induced reperfusion injury after cardiac arrest of 15 minutes in dogs. The cerebral and pulmonary reperfusion injury during deep hypothermia CPB was less than during mild hypothermia, whereas the cardiac reperfusion injury during mild hypothermia, CPB was less than during deep hypothermia.

**Keywords:** cardiopulmonary arrest; cardiopulmonary bypass (CPB); cardiopulmonary resuscitation (CPR); free radicals; hypothermia; malondialdehyde (MDA); nitrogen monoxide (NO); reperfusion injury; superoxide dismutase (SOD)

**Hospital Disaster Preparedness at a Government-Designated Core Disaster Hospital**

Kiyoshi Ishikawa: Koji Sato; Mitsuki Tanaka; Nami Tojo
Nagoya Daini Red Cross Hospital, Japan

After the Great Hanshin-Awaji earthquake in 1995, the Japanese government designated core disaster hospitals in each prefecture. Nagoya Daini Red Cross Hospital is one of the core hospitals, and should meet the following requirements: (1) have a durable structure; (2) strong life-line facilities; (3) ample storage of medical supplies and equipment; (4) be prepared to accept many disaster casualties; (5) ability to dispatch rescue squads immediately; and (6) have hospital disaster plans and conduct full disaster drills regularly.

In 2001, a new emergency and critical care center of the hospital was established in order to fulfill the role and responsibility as the core hospital. The structure of the center consists of six stories above-ground and two stories below-ground level. It was constructed in such a way that it would withstand an earthquake of the size of the Great Hanshin-Awaji quake. In the second basement level is the energy center where the life-line facilities are kept. These include electricity and water supplies that can be provided for three days to in-hospital patients, disaster casualties, and hospital staff. The Emergency Outpatient Department on the first floor is large enough to treat many disaster casualties simultaneously.

As for human-related disaster preparedness, disaster relief drills are conducted regularly to encourage the staff to know how to act should a disaster happen. The planning of a disaster relief drill is the most important part of the hospital plan. Disaster preparedness at Nagoya Daini Red Cross Hospital, as a core designated disaster hospital, will be described in this paper.
