Non-polyol low-digestible carbohydrates: food applications and functional benefits

Olive Murphy*

Leatherhead Food Research Association, Randalls Rd, Leatherhead, Surrey, KT22 7RY, UK

Many LDCs currently on the market are not digested in the upper gastrointestinal tract and become fermented in the large intestine. They possess physiological benefits similar to those of dietary fibre. For some of these materials the fermentation process is highly specialised and leads to the selective stimulation and growth of beneficial gut bacteria, e.g. bifidobacteria. These materials are described as prebiotics, which are defined as nutrients fermented in the large bowel that favour the growth of desirable large bowel microflora. This activity has been demonstrated for inulin and oligofructose. Two other carbohydrates with low digestibility that offer desirable physiological properties are resistant starch (RS) and polydextrose (PD). These ‘functional’ benefits have led to considerable interest from the food industry leading to the use of these ingredients in the development of new ‘healthy’ products. This paper describes the use of these materials in the development of ‘healthy’ products, some of their functional properties, and the benefits they confer on different food systems.

Inulin: Oligofructose: Polydextrose: Resistant starch: Functional foods

Since the 1980s the ‘healthier’ food and drinks market has been transformed from a specialist area into a mainstream market. In Europe developments have been led by the UK where the market was valued at £6.7 billion in 1997 with dairy products as the largest sector (Comber, 1999). Whereas products marketed as ‘low-fat’ or ‘sugar-free’ have proved most popular, there has been a developing consumer interest in functional products that contain added ingredients and provide specific health benefits (Young, 1998; Hilliam, 1998). In terms of the functional foods market, the UK was the largest market in Europe, worth an estimated £703 million in 1997 (Comber, 1999) (Table 1). This included products perceived by consumers as functional foods even if they did not make specific health claims. A product audit survey carried out by the Leatherhead Food Research Association in the same year looked at the availability of functional foods in different European countries and identified that the most frequent claim used was that relating to ‘gut health’ and the digestive system (Hilliam et al. 1997) (Table 3).

The popularity of these products reflects nutritional guidelines recommending increased dietary fibre intake since low fibre consumption has been implicated as a risk factor in many diseases (British Nutrition Foundation, 1990). Insoluble fibre ingredients, such as bran, have traditionally been used in products such as breakfast cereals, breads and pasta, but the palatability of these materials has limited the level that can be incorporated into different systems. Soluble fibre ingredients are currently of greater interest in the formulation of ‘healthy’ foods because they are more palatable. In addition, some can be used in food systems to thicken, add viscosity or gel (Dreher, 1999).

Inulin

Inulin is a natural food ingredient found in many vegetables and obtained industrially from chicory roots (Van Loo, 1995). It is a polydisperse mixture of molecules all with the same basic chemical structure, which can be symbolised as GFn, where G is the glucosyl moiety, F is the fructose moiety and n equals the number of fructose moieties linked by β(2→1) linkages (Fig. 1). The degree of polymerisation (DP) of inulin typically ranges from 3 to 60. Inulin extracted from chicory roots contains up to 10% of mono- and disaccharides, mainly sucrose and fructose, and an oligosaccharide content (DP=10) of approximately 30% (Niness, 1999). These products have a low residual sweetness due to mono-, di- and oligosaccharides.

The production process of inulin includes the extraction of the naturally occurring inulin from chicory roots by diffusion in hot water, followed by refining and spray drying. Inulin from which the lower DP-fraction has been physically removed and with an average DP of 25 is available for high-performance fat replacement (Franck, 1997).

The nutritional properties of inulin are based on three factors.

1. Upon ingestion, inulin is not broken down by the human digestive system and for the purpose of food labelling it is recommended that it should be given an energy value of 6·28 kJ/g (Roberfroid, 1999a).

2. Inulin is fermented by colonic bacteria causing an increase in faecal biomass, production of short-chain fatty acids and decrease in caecocolonic pH and may therefore be classed as a dietary fibre (Roberfroid, 1993).

3. Ingestion of inulin results in a significant increase of bifidobacteria in the colon and inhibits the growth of less beneficial bacteria (Roberfroid et al. 1998; Roberfroid, 1999b; Van Loo et al. 1999; Kruse et al. 1999).

Using these ingredients in food formulations allows the nutritional value of the endproduct to be improved by increasing the dietary fibre content, reducing the calorie content and increasing the bifidus-promoting capacities.

The recent interest in these ingredients also results from their interesting technological characteristics. Inulin has a neutral taste, is colourless and has minimal influence on the organoleptic characteristics of a product. Combining inulin with high intensity sweeteners significantly improves the taste of products giving a more sugar-like sweetness. Owing to the high solubility of this ingredient over classical fibres’ inulin can be used to fortify dairy products such as milk drinks, yoghurt, cheeses and desserts, which have been traditionally difficult to fortify (Niness, 1999).

The functionality of inulin is based on its effect on water solutions at various solid levels. At lower concentrations it causes significant viscosity increase and can be used as a rheology modifier. At a concentration of 40–45% an inulin gel or crème is formed which is firm but with a fatty creamy feel. This crème offers many advantages. Water is tightly bound in the gel, helping to maximise freeze–thaw stability and to inhibit syneresis. In this form inulin is stable in acidic conditions or at high temperatures owing to lack of available water (Silva, 1996). This has created the opportunity for use in ‘reduced fat’ mayonnaise and salad dressings. It can be used in fat-free products to give a smooth creamy texture and taste. It allows the manufacturer to replace fat containing 37·6 kJ/g with an inulin/water combination which has an energy value of 2·09 kJ/g or less, resulting in significant calorie reduction (Wouters, 1998).

Inulin has been successfully applied in fat-reduced table spreads, cheese products, meat products, frozen desserts, fillings, sauces and meat replacers (Franck, 1997). Specific applications include the following.

1. Table spreads: both fat and water form a continuum with inulin, so that inulin can both replace significant amounts of fat and stabilise the emulsion while providing a short spreadable texture.

2. Breads: inulin crème can be used to increase water addition in doughs as well as moisture retention.

3. Chocolate: inulin can be used as a sucrose replacer, especially when combined with fructose or polyols.

4. Ice cream: inulin functions as an inhibitor of water crystal growth.

5. Dairy-based mousses: the incorporation of 1–5% inulin enables the product to retain its structure for a longer time and gives a rich fat-like mouthfeel.

Oligosaccharides

Oligosaccharides of various types are found in many common foods including fruit, vegetables, milk and honey (Van Loo, 1995; Van Loo et al. 1995). The possible health benefits associated with the consumption of these compounds have led to their increased popularity as food ingredients.

Oligosaccharides are generally defined as glycosides having between three and ten simple sugars linked together (Fig. 1) and often contain low levels of monosaccharides...
and di- or polysaccharides. The properties of these materials depend on their chemical structure, molecular weight and levels of mono- and disaccharides. For example, low-molecular-weight ingredients can alter food-freezing temperature. Longer chain oligosaccharides can increase body and mouthfeel and are useful in beverages or as fat replacers. However, it is the physiological properties of these materials that have created the most interest, these being their reduced energy value, potential hypocalorific and bifidogenic properties and dietary fibre like effects (Playne & Crittenden, 1996; Roberfroid, 1993).

Fig. 1. Structure of some non-polyol low-digestible carbohydrates. (a) Fructo-oligosaccharide: e.g. inulin, $n=2–60$; oligofructose, $n=2–20$. (b) Polydextrose. (c) Galacto-oligosaccharide.
There are currently approximately 12 classes of food grade oligosaccharides in commercial production (Table 4). Most are either synthesised from simple sugars, such as sucrose or lactose, or they can be formed by the controlled hydrolysis of starch or other polysaccharides. Of these, lactose is used as the starting material for the three oligosaccharides: galacto-oligosaccharide, lactulose and lactosucrose (Fig. 1). Galacto-oligosaccharides are found naturally in human milk (McVeagh & Miller, 1997) and have been associated with the establishment of bifidus flora in breast-fed infants (Rubaltelli et al., 1998). The inclusion of galacto-oligosaccharides as prebiotic food ingredients has attracted considerable commercial interest and they are now manufactured commercially. Lactulose is produced by the conversion of the glucose moiety in lactose into a fructose residue. Lactulose is completely malabsorbed in the upper intestine and it is suggested that it has some prebiotic effects (Kontula et al., 2000). It is used predominantly as a pharmaceutical in the treatment of constipation and hepatic encephalopathy (Bircher et al., 1966; Clausen & Mortensen, 1997), but there is emerging interest in its bifidogenic effects when included in infant milk formulas (Baskaran et al., 1999). The trisaccharide lactosucrose is an oligosaccharide with potential bifidogenic effects and is derived from lactose in which a lactose molecule has a fructose moiety joined at the glucose residue by a $\beta(2\rightarrow1)$ glycosidic bond (Fujita et al., 1992).

Fructo-oligosaccharides represent one of the major classes of bifidogenic oligosaccharides in terms of production volume (Tomomatsu, 1994). They are manufactured by two different processes which result in slightly different endproducts. In the first method, they are produced from sucrose by transfructosylation and the fructo-oligosaccharide formed contains between two and four $\beta(2\rightarrow1)$-linked fructosyl units linked to the terminal $\alpha-D$-glucose residue. The second method used for fructo-oligosaccharide production is the controlled enzyme hydrolysis of inulin. Not all of the $\beta(2\rightarrow1)$-linked fructosyl chains end with a terminal glucose and the oligosaccharide mixture produced contains longer fructo-oligomer chains than that produced by the sucrose transfructosylation process (Crittenden & Playne, 1996). From a chemical point of view there is almost no difference between inulin and fructo-oligosaccharides. They are both oligomers of fructose, the monomers being linked by $\beta(2\rightarrow1)$ glycosidic bonds. Whereas inulin has a distribution of molecules with chain lengths of 2–60 units, the chain lengths for oligofructose range from two to ten units with an average DP of 4 (Niness, 1999).

Oligofructose is used to modify the nutritional and organoleptic properties of foods particularly low-calorie foods and those with specific effects on gut function. Such effects are based on the physiological and functional characteristics of these materials. For the purpose of food labelling it is recommended that oligofructose (as with inulin) is given an energy value of 6.28 kJ/g (Roberfroid, 1999a), although human studies suggest an energy value of 9.5 kJ/g (Molis et al., 1996). Studies have shown that these materials are selectively fermented in the colon by bifidobacteria, which subsequently grow at the expense of less beneficial bacteria (Tomomatsu, 1994; Gibson & Roberfroid, 1995).

Oligofructose possesses functional qualities similar to those of sugar or glucose syrup. It is more soluble than sucrose and provides 30–50% of the sweetness of table sugar. Oligofructose is often used in combination with high intensity sweeteners to replace sucrose, provide a balanced sweetness profile and mask the aftertaste of aspartame or acesulfame K (Wiedmann & Jager, 1997). Oligofructose is hygroscopic and has humectant properties (De Soete, 2000). Examples of its use in food products include the following.

1. Light jam products: oligofructose can be used as the sole sweetening agent and gives 34% calorie reduction compared with the sucrose standard. Organolep-
tic characteristics of the products are claimed to be very similar, with the test sample having a lower sweetness and a softer texture.

(2) Ice cream: oligofructose can be used with inulin to replace all the sugar and reduce the fat content and give excellent mouthfeel characteristics. Since the freezing point depression is less with oligofructose than with sugar, the texture can be harder.

(3) Confectionery applications: hard candies, gums and marshmallows can be made while achieving significantly reduced energy values.

**Resistant starch**

Another class of carbohydrates with low digestibility that has increased in popularity in recent years owing to its physiological and functional characteristics is resistant starch (RS) (Yue & Waring, 1998). RS may be defined as the sum of starch and products of starch degradation not absorbed in the small intestine and classified as RS that is physically inaccessible to amylase (RS1), naturally resistant or gelatinised starch (RS2) and retrograded starch (RS3) (Wisker, 2000). In cereals, four classes of RS have been identified, these being native starch, retrograde amylase, the amylolipid complex and encapsulated gelatinised starch (Bornet, 1993). RS is fermented by large bowel microflora and may be classified as a dietary fibre (Asp, 1993). Furthermore, colonic fermentation of RS (in common with non-starch polysaccharides and oligosaccharides) produces short-chain fatty acids, notably butyric acid (Jenkins et al. 1988) which has reportedly significant antineoplastic effects in vitro and in vivo (Vanmunster & Nagengast, 1993). There is growing evidence that butyric acid has a protective role in the development of colorectal cancers (Scheppach et al., this issue).

RS can be found in both unprocessed foods such as raw potatoes and bananas (Kingman & Englyst, 1994; Wisker, 2000) and in processed foods such as pasta and bread (Brighenti et al. 1988). Although highly discussed in the 1980s, no significant attempts were made to commercialise RS until the 1990s. Commercial RS food-grade products are obtained by the controlled retrogradation of partially hydrolysed amylose leading to the formation of insoluble crystallites.

The processing technology involved allows distinct physical and functional properties to be achieved. Owing to its white colour, bland taste and microparticulate structure, RS can be easily incorporated in food without altering the texture and appearance. It can be used as a fat mimetic or to increase the dietary fibre content of food (Würsch, 1999).

Incorporation of RS may result in positive textural enhancement of low moisture foods, such as crackers and cookies. In extruded cereals, RS contributes greater crispness and better expansion. In pasta products the use of RS can increase the total fibre content while avoiding the grainy or discoloured appearance that results from the inclusion of commonly used fibres (Ranhotra et al. 1999).

**Polydextrose**

Polydextrose (PD) is now used widely across most sectors of the food industry. It is a randomly bound polymer of glucose containing small amounts of sorbitol and citric acid (Moppett, 1991) (Fig. 1). The original polydextrose has been subject to various clean up procedures to produce several qualities of material.

The random bonds in the PD polymer prevent mammalian digestive enzymes from readily hydrolysing the molecule and it has a reported reduced energy value of 4·18 kJ/g (Fgdor & Rennhard, 1981). However, the metabolisable energy value of PD is higher compared to values obtained by radiochemical balance procedures (Cooley & Livesey, 1987). It is an odourless, white to cream amorphous powder with virtually no sweetness. PD takes part in the Maillard reaction and so allows characteristic caramel and toffee colours to develop.

PD is highly soluble in water (approximately 80% w/w at 20°C) and solutions have a higher viscosity than sucrose or sorbitol solutions at equivalent concentrations and temperatures. This characteristic enables PD to provide the desirable mouthfeel and textural qualities when replacing sugars and fats. For example, in spoonable and pourable dressings with reduced levels of oil, it provides some of the functionality of the oil by providing mouthfeel, viscosity and bulk (Kappas et al. 1993).

An important characteristic of PD is that it has water activity closely resembling that of sucrose and can function as a humectant helping to slow down undesirable changes in the moisture content of foods. This prolongs shelf-life. In short crust pastry, the fat content can be reduced by up to 50% with the addition of polydextrose while maintaining the texture normally associated with traditional full-fat pastry. Its addition can increase crispness, reduce pastry shrinkage and improve the machinability of very thin sheets of dough without affecting the organoleptic quality of the product.

PD can be used to replace both sucrose and fat in chocolate and toffee confectionery (Zumbe et al., this issue). This has led to the development of ‘light’, reduced-calorie and ‘tooth-friendly’ products which utilise hydrogenated PD that does not contain residual cariogenic monosaccharides. In chocolate, PD contributes good taste characteristics and balances the taste profile of polyol-based sugar-free chocolate. Since PD has a higher viscosity than simple sugars and polyols at equivalent concentrations, it can contribute to the creamy mouthfeel of products (Mitchell, 1996).

**Conclusion**

The market for LDCs is substantial and continues to expand. This has been encouraged by an increased consumer awareness of the health benefits of consuming higher levels of dietary fibre. Although dominated by Japanese companies, European interest is growing rapidly and a wide variety of products displaying novel physiolo-
gical and functional characteristics has emerged. As the beneficial functional properties of LDCs become more widely understood, both the volume of use and the diversity of applications are expected to increase. Further developments in the carbohydrate materials themselves are in progress and it is likely that more novel ingredients demonstrating new physiological effects will emerge over the next few years. At present, materials possessing dietary fibre effects and prebiotic activity are popular and their use in symbiotic products containing probiotic bifidobacteria and prebiotic oligosaccharides is one of the largest emerging markets.
