Prognostic association of cardiac anxiety with new cardiac events and mortality following myocardial infarction

Background
General anxiety and depressive symptoms following a myocardial infarction are associated with a worse cardiac prognosis. However, the contribution of specific aspects of anxiety within this context remains unclear.

Aims
To evaluate the independent prognostic association of cardiac anxiety with cardiac outcome after myocardial infarction.

Method
We administered the Cardiac Anxiety Questionnaire (CAQ) during hospital admission (baseline, n = 193) and 4 months (n = 147/193) after discharge. CAQ subscale scores reflect fear, attention, avoidance and safety-seeking behaviour. Study end-point was a major adverse cardiac event (MACE): readmission for ischemic cardiac disease or all-cause mortality. In Cox regression analysis, we adjusted for age, cardiac disease severity and depressive symptoms.

Results
The CAQ sum score at baseline and at 4 months significantly predicted a MACE (HRbaseline = 1.59, 95% CI 1.04–2.43; HR4-months = 1.77, 95% CI 1.04–3.02) with a mean follow-up of 4.2 (s.d. = 2.0) years and 4.3 (s.d. = 1.7) years respectively. Analyses of subscale scores revealed that this effect was particularly driven by avoidance (HRbaseline = 1.23, 95% CI 0.99–1.53; HR4-months = 1.77, 95% CI 1.04–1.83).

Conclusions
Cardiac anxiety, particularly anxiety-related avoidance of exercise, is an important prognostic factor for a MACE in patients after myocardial infarction, independent of cardiac disease severity and depressive symptoms.

Potential factors that determine cardiac prognosis after a myocardial infarction include demographic and clinical parameters, health behaviours and psychiatric morbidities. Recently, the impact of anxiety symptoms on cardiac prognosis in patients with heart disease has gained more attention. In a meta-analysis, post-myocardial infarction anxiety was associated with a 36% increased risk of adverse cardiac outcomes. Although this meta-analysis could not adjust for measures of disease severity, effect estimates of included studies that did adjust for measures of disease severity were only slightly or not attenuated. Also, generalised anxiety disorder (GAD) was related to adverse outcomes in patients with myocardial infarction and this relationship was not explained by cardiac disease severity parameters. In contrast, other studies described no association or even a beneficial association in patients with myocardial infarction and those with stable coronary artery disease (CAD) between anxiety and cardiac prognosis. Furthermore, a recent study in patients with CAD undergoing coronary artery bypass graft surgery showed different associations of different types of anxiety with cardiac prognosis: no association of fear and panic disorders and their symptom dimensions, but an adverse association with GAD. These controversial findings suggest that different types of anxiety may be related differently to cardiac prognosis. As it remains unclear which specific aspects of anxiety are associated with cardiac prognosis, the need to examine the unique contribution of types of anxiety on cardiovascular risk has been advocated. Recently, a population-based study found that worry predicted non-fatal cardiac outcome over a 3-year follow-up, whereas panic and phobia did not. Another population-based study suggested that in women phobic anxiety may predict fatal but not non-fatal cardiac events.

After a myocardial infarction, cardiac stimuli and sensations may trigger specific anxiety symptoms, conceptualised as cardiac anxiety. This can be assessed reliably by the Cardiac Anxiety Questionnaire (CAQ). CAQ subscale scores in patients with myocardial infarction reflect fear, attention, avoidance and safety-seeking behaviour. Higher cardiac anxiety is shown to be associated with lower quality of life in patients with myocardial infarction. To our knowledge, the association between cardiac anxiety and cardiac outcome has not been examined previously. Furthermore, in most studies anxiety symptoms are measured directly after hospital admission or surgery, which may inflate the rates of psychopathology as a result of the temporary distress of admission to hospital. Long-term functional outcome may only be affected by psychopathological symptoms that persist, or develop during the first weeks as has been demonstrated for depressive symptoms. Previously, we showed that trajectories of cardiac anxiety after a myocardial infarction are largely determined within the first 3–4 months after the event. The aim of the present study was to explore the impact of self-reported cardiac anxiety at both admission to hospital and at 4 months after discharge on cardiac prognosis after a myocardial infarction. We hypothesised that patients reporting elevated symptoms of cardiac anxiety had the worst cardiac prognosis independent of potential confounders like cardiac disease severity and depressive symptoms.

Method
For the present analysis we included patients with myocardial infarction enrolled in an exploratory prospective cohort study.
described previously.\textsuperscript{15} Patients consecutively admitted to hospital with myocardial infarction between November 2006 and December 2007 to the Department of Cardiology of Radboud University Medical Centre, The Netherlands, were recruited within 2 days of admission. Eligible patients had to be diagnosed with ST-elevated myocardial infarction (STEMI) or non-ST-elevated myocardial infarction (NSTEMI). The diagnosis was confirmed by the presence of a rise and fall of troponin I (>0.20 \( \mu \text{g/L} \)).

Exclusion criteria were: age above 85 years, discharge from hospital within 2 days of admission, and inability to fill out questionnaires (because of insufficient knowledge of the Dutch language, cognitive impairment or being too ill to participate). The study protocol was approved by the local medical ethics committee, and all patients provided written informed consent.

**Procedure**

Between days 2 and 7 after admission (baseline), patients completed a set of self-report questionnaires including the CAQ\textsuperscript{13,14} and the Beck Depression Inventory (BDI).\textsuperscript{17} Four months after discharge patients were sent the same questionnaires by post. If necessary, patients were contacted by phone as a reminder.

**Measures**

**Assessment of cardiac anxiety**

Cardiac anxiety was assessed with the 18-item self-report-questionnaire CAQ, rating each item on a five-point Likert scale ranging from 0 (never) to 4 (always).\textsuperscript{13} In line with previous publications, the overall score as well as subscale scores are expressed as an average item score, which was computed by summing the score for the relevant items and dividing it by the number of items. The CAQ is well-validated in different populations, originally by Eifert et al.\textsuperscript{13,14,18} Recently, we cross-validated the CAQ in patients with myocardial infarction and identified a factor structure of four subscales: assessing fear (for example, ‘When I have chest discomfort, or when my heart is beating fast: I get frightened’), attention (for example, ‘I pay attention to my heartbeat’), avoidance of (physical) activity (such as, ‘I avoid activities that make my heart beat faster’) and safety-seeking behaviour (such as, ‘When I have chest discomfort or when my heart is beating fast, I like to be checked out by a doctor’), respectively.\textsuperscript{14} Our study showed a good internal consistency of both total and subscale scores (Cronbach \( \alpha = 0.84 \) and 0.6–0.9, respectively), a high test–retest-reliability (0.88, \( P < 0.001 \)) and low to moderate correlations with questionnaires such as the Agoraphobic Cognitions questionnaire (0.31), the State–Trait Anxiety Inventory (0.39) and the Beck Depression Inventory (BDI, 0.27). Comparable results, including the four subscales, have been previously reported in an independent cross-validation study in 658 people referred for screening for coronary artery disease.\textsuperscript{18} We confirmed the four subscales factor solution on the present data. In the present study, our main predictors were the continuous overall mean item score of the CAQ (i.e. total score divided by number of items), as well as the mean item score of the subscales.

**Assessment of covariates**

Sociodemographic and cardiac-related variables

Sociodemographic and clinical data concerning the severity of the cardiac disease (left ventricular ejection fraction (LVEF) and a history of myocardial infarction), as well as relevant cardiac risk factors (including smoking, hypertension, hypercholesterolemia, diabetes mellitus, history of stroke, peripheral atherosclerotic disease, history of cardiac disease other than myocardial infarction) were collected by the cardiologist during the admission to hospital for the myocardial infarction. LVEF was determined by echocardiography according to the modified Simpson’s rule.\textsuperscript{19} Information on possible treatment with percutaneous coronary intervention (PCI) and assignment for cardiac rehabilitation after admission was retrieved from the hospital files.

**Psychiatric comorbidity**

Anxiety often coincides with depression in patients with myocardial infarction.\textsuperscript{20} Two meta-analyses have identified depression in individuals with myocardial infarction as a risk factor for all-cause mortality, cardiac mortality and cardiac events.\textsuperscript{21,22} In order to adjust for depression as a covariate, depressive symptoms were measured with the BDI, a 21-item self-report questionnaire rating each item on a four-point Likert scale, which is well-validated in people with myocardial infarction.\textsuperscript{23,24}

**Assessment of adverse outcomes**

The primary outcome was a major adverse cardiac event (MACE), defined by all-cause mortality or a readmission for a major cardiac event, occurring after the CAQ assessment at baseline or 4 months after discharge, respectively. Hospital readmissions with discharge diagnoses with ICD-9 codes 410, 411, 413, 414 (ischemic heart disease); 427.4 (ventricular fibrillation and flutter), 427.5 (cardiac arrest) and/or readmissions for an acute (unplanned) coronary intervention (coronary artery bypass graft/ percutaneous coronary intervention) were included as a major cardiac event.\textsuperscript{24} Data on all-cause mortality were obtained up until 1 January 2013 from the Dutch Central Bureau of Statistics by linkage to the municipal personal records database. Data concerning hospital admissions came from the Dutch national registry of hospital discharges and were obtained up until 1 January 2012 from the Dutch Central Bureau of Statistics by linkage to the municipal personal records database. Furthermore, in order to obtain more complete data, we also examined the administration and patient records of the Radboud University Medical Centre on readmissions for a MACE and/or mortality. These data were obtained up until 1 January 2013.

**Statistical analysis**

Multiple imputation model

In order to use all available data for survival analysis, we performed multiple imputations in patients with data on a MACE. Rubin’s rules were used to pool the data.\textsuperscript{25} Linear and logistic regression for multiple imputations was performed with all variables to be included in the final analysis model, as well as other relevant variables that were not included in the analyses, including cardiac risk and disease variables, PCI treatment and assignment to cardiac rehabilitation. These variables were examined for normal distribution and, if needed, transposed before the imputation was run; BDI was natural log-transformed. In total, 7.0% of all values in the imputation model were missing. A total of 67 data-sets were created, because 67.0% of the cases had at least one missing value.\textsuperscript{26} For each imputed file, SPSS estimated the missing values in 100 iterations.
Baseline demographic and clinical characteristics were compared between patients with and without a MACE with logistic regression (for categorical variables), Student’s t-test, or when continuous variables were not normally distributed with the Mann–Whitney U-test.

Correlation and survival analysis.

The correlation between sum scores of the CAQ and the BDI was evaluated with Spearman’s rho. For the survival analysis, Cox regression was used to evaluate risk of a MACE associated with CAQ sum scores at baseline and at 4 months after discharge. Baseline characteristics, CAQ subscales at baseline and at 4 months after discharge with MACE was evaluated. For analyses with CAQ at admission to hospital as determinant, the follow-up period for primary end-point started at admission to hospital for the index myocardial infarction. For analyses with CAQ at 4 months after index myocardial infarction as determinant, the follow-up period for the primary end-point started at the date of this CAQ assessment. In all analyses the follow-up period for primary end-points ended on 1 January 2013, and patients who did not have the outcome of interest until 1 January 2013 were censored on 1 January 2013.

In the basic model, adjustments were made for age and gender. A priori we decided to adjust for a history of myocardial infarction and LVEF as objective parameters of cardiac disease severity, as both have been shown to be consistently related to worse cardiac prognosis. In addition, since cardiac-related hospital readmissions between baseline and 4 months also reflect cardiac disease severity, we adjusted for this characteristic when examining the CAQ score at 4 months after discharge. In the final model, we also adjusted for BDI scores.

### Results

#### Sample

Of 398 people with myocardial infarction admitted to the cardiology ward, 135 patients were, after a primary PCI, relocated to a hospital in their home area within 2 days of admission. Of the 263 patients who were still present at the time we asked for informed consent, 203 patients (77%) agreed to participate. Ten individuals had to be excluded because of missing data on a MACE, leaving 193 patients to be analysed for the association between CAQ at baseline and a MACE. Baseline characteristics, resulting from the imputational model, for the 193 patients stratified according to occurrence of a MACE are shown in Table 1. Four people died before the assessment 4 months after discharge, leaving 189 people to be analysed for the association between CAQ at 4 months after discharge and a MACE.

The mean duration of assessment of CAQ and BDI at baseline was 3.7 days (s.d. = 3.8) from admission to hospital (or index event (MACE) (yes/no))

myocardial infarction). The next CAQ assessment took place 138.8 days (s.d. = 59.4) from admission to hospital (i.e. about 4 months post-myocardial infarction). A total of 77.8% of patients (n = 147/189) completed the CAQ at follow-up. Sum scores of CAQ and BDI were moderately correlated at admission to hospital (Spearman’s r = 0.332, P < 0.001) and highly correlated at 4 months after discharge (P = 0.501, P < 0.001).

Predictors of a MACE

During a mean follow-up period of 4.2 years (s.d. = 2.0) (range 0–6.6 years), 77 (39.9%) of 193 patients had a MACE after baseline. A total of 36 of them (46.8%) died. During a mean follow-up period of 4.3 years (s.d. = 1.7) (range 0–6.0 years), 67 (35.4%) of 189 patients had a MACE after the 4-month CAQ assessment. A total of 32 of them (47.8%) died. Patients who had an event during the follow-up period were older (P < 0.001), had higher CAQ scores at baseline (P = 0.020) and 4 months after the index myocardial infarction (P = 0.004), had higher BDI scores at 4 months after the index myocardial infarction (P = 0.002), were more likely to have a history of myocardial infarction and cardiac disease other than myocardial infarction (P < 0.001), or diabetes mellitus (P = 0.003) and were less likely to be assigned to cardiac rehabilitation (P = 0.004) (Table 1).

CAQ sum score and risk of a MACE

CAQ at baseline was significantly associated with a higher risk of a MACE, independent of age and gender, LVEF and cardiac history, and BDI. CAQ at 4 months after discharge was also significantly associated with a higher risk of a MACE, even when adjusted for age, gender, LVEF, cardiac history, cardiac-related hospital readmissions between the index event and CAQ assessment and BDI (see Table 2 for hazard ratios (HRs) with 95% confidence intervals).

Subscales of CAQ at 4 months after discharge and risk of a MACE

Only the subscale ‘Avoidance’ at 4 months after discharge was significantly associated with a MACE independent from all previously mentioned covariates. The prognostic association of ‘Avoidance’ at baseline lost significance after adjusting for severity of cardiac disease (see Table 3 for hazard ratios with 95% confidence intervals).

Sensitivity analyses for potential cardiac risk factors

In sensitivity analyses, we tested whether characteristics that differed at baseline between patients with and without a MACE and that were not included in our model, might have influenced our results. Adding these variables (see Table 1) to model 2 generally did not affect the association between overall CAQ score and adverse prognosis. The only exception was the presence of a history of cardiac disease other than myocardial infarction: in this model the hazard ratio for CAQ at baseline and a MACE was attenuated to just be non-significant (HR = 1.43; 95% CI 0.96–2.11, P = 0.076).

Sensitivity analyses for gender differences in overall CAQ score and risk of a MACE

We found an interaction effect between gender with overall CAQ score in the prognostic model (included variables: CAQ, gender, age, interaction gender–CAQ) at baseline (HRbaseline = 2.16, 95% CI 1.03–4.56, P = 0.043; HR4-months = 2.78, 95% CI 1.00–7.72, P = 0.050). Stratified analyses showed larger hazard ratios and more significant results in the women compared with the men. Only in women, did the full model remain significant for the CAQ at baseline (HR = 3.04, 95% CI 1.47–6.28, P = 0.003, n = 64 of which n = 31 had a MACE during follow-up), whereas the hazard ratio for the CAQ at 4 months lost significance after additional adjustment for BDI (HR = 2.17 (95% CI 0.78–6.07), P = 0.139, n = 62 of which n = 27 had a MACE during follow-up, see online Tables DS1–3).

Discussion

Main finding

This study was the first to address the independent prognostic association of cardiac anxiety following myocardial infarction with adverse cardiac prognosis. Patients reporting higher cardiac anxiety were at increased risk of an adverse prognosis after adjustment for age, gender, cardiac disease severity parameters and depressive symptoms; with each point increase on the CAQ, which has a possible range of 0 to 4, the risk of a new cardiac event increased from 56% (at baseline) to 71% (at 4 months after discharge). This effect seemed to be particularly driven by avoidance behaviour.

Our findings are in line with previous research reporting the prognostic impact of anxiety1 and anxiety disorders24,29,31 in patients with myocardial infarction. These heterogeneous studies used different anxiety measures and the reported hazard ratios in the meta-analysis (around 1.30)31 were based on dichotomous cut-off points of anxiety (present or not) that makes it difficult to compare the reported hazard ratios with ours. One study evaluated the prognostic association of separate dimensions of anxiety in patients with myocardial infarction. It also described an adverse prognostic association: significant associations for

CAQ 4 months after discharge = 67 of a total n = 189 had a MACE

Model 1: unadjusted; Model 2: adjusted for age and gender; Model 3: Model 2 + left ventricular ejection fraction and a history of myocardial infarction, in line with previous studies on this topic. However, since cardiac anxiety was inversely correlated with cardiac disease severity, as previously reported by our group,40 it seems unlikely that our results are driven by residual confounding because of cardiac disease severity. In our study, after adjustment for parameters of cardiac disease severity, the association of cardiac anxiety with a MACE remained significant. More importantly, the hazard ratios hardly attenuated, implying a prognostic effect of cardiac anxiety independent from cardiac disease severity. Adjustment for depressive symptoms did not affect the effect size of the cardiac anxiety on adverse cardiac prognosis. This is consistent with other studies assessing the association between general anxiety or anxiety disorder and cardiovascular events independent from depression.2,31,33

### Potential mechanisms

The association between anxiety and ischemic heart disease might be explained by both behavioural and biological mechanisms. First, anxiety appears to be associated with unhealthy behaviour (for example, physical inactivity and smoking) in individuals at risk of coronary heart disease.44 Our finding that the main prognostic effect of cardiac anxiety was driven by the subscale showing the most specific results for avoidance behaviour related to cardiac stimuli, especially at 4 months after discharge.

In our study, after adjustment for several important confounders simultaneously. Nonetheless, we were not able to address all indicators of cardiac disease severity. Therefore, we adjusted for the two most important indicators, LVEF and a history of myocardial infarction, in line with previous studies on this topic. However, since cardiac anxiety was inversely correlated with cardiac disease severity, as previously reported by our group,40 it seems unlikely that our results are driven by residual confounding because of cardiac disease severity. In line with previous studies we chose as primary outcome a combination of all-cause mortality and cardiac readmissions. However, whereas previous studies included a rather broad range of cardiovascular events,1,2,23 we only included readmissions for somatic anxiety (HR = 1.29) and total anxiety (HR = 1.38), with a trend for psychological anxiety.23 However, these anxiety dimensions were derived from a questionnaire assessing general anxiety (Hamilton Anxiety and Depression Rating Scales) and all dimensions are more or less associated with avoidance behaviour. These general findings are extended by our findings showing the most specific results for avoidance behaviour related to cardiac stimuli, especially at 4 months after discharge.

In our study, after adjustment for parameters of cardiac disease severity, the association of cardiac anxiety with a MACE remained significant. More importantly, the hazard ratios hardly attenuated, implying a prognostic effect of cardiac anxiety independent from cardiac disease severity. Adjustment for depressive symptoms did not affect the effect size of the cardiac anxiety on adverse cardiac prognosis. This is consistent with other studies assessing the association between general anxiety or anxiety disorder and cardiovascular events independent from depression.2,31,33

### Methodological considerations

A strength of the present study is that cardiac anxiety was assessed not only at admission to hospital but also at 4 months after the infarction, when the possible inflating impact of the stressful admission to hospital and the event itself on anxiety parameters is expected to have settled down.12 Importantly, although our sample size was relatively small, it was large enough to adjust for several important confounders simultaneously. Nonetheless, we were not able to address all indicators of cardiac disease severity. Therefore, we adjusted for the two most important indicators, LVEF and a history of a myocardial infarction, in line with previous studies on this topic. However, since cardiac anxiety was inversely correlated with cardiac disease severity, as previously reported by our group,40 it seems unlikely that our results are driven by residual confounding because of cardiac disease severity.
acute ischemic events. We consider this as an advantage. As patients with high cardiac anxiety might be more likely to consult their doctor and be admitted to the hospital with cardiac complaints, this might partly explain the association between cardiac anxiety and cardiovascular-related hospital readmissions. By only including readmissions because of acute ischemic events, this risk is minimised.

Although the prognostic association of cardiac anxiety with a MACE was particularly driven by avoidance of physical activity, it is important to realise that physical activity was not assessed in the present study and some of the other dimensions of cardiac anxiety (fear and attention, respectively) showed even higher hazard ratios than avoidance. The prognostic associations of these subscales were not significant in the final model, but this may be explained by a power problem (type two error). Studies in larger populations are needed to examine this more closely. Future studies should include physical activity as a mediating mechanism when studying the prognostic impact of cardiac anxiety.

Limitations of the present study include the absence of information on presence (and/or history) of a formal diagnosis of an anxiety and/or depressive disorder, nor did we have information on possible psychiatric treatment. Therefore, we do not know how cardiac anxiety is related to psychiatric diagnosis. As (some) anxiety disorders have been associated with the development of coronary heart disease in the general population and prognosis in patients with heart disease, this would have been interesting. Nevertheless, we did adjust for depressive symptoms, which is an important possible confounder.

Our study had a good response rate of 77%, even though we had to exclude the most severely ill patients. On the other hand, patients with milder symptoms, who were transported to other hospitals within 2 days, were not eligible for the present study and it is questionable whether this limits generalisation of our results.

In our study, the association between cardiac anxiety and adverse prognosis could not be explained by cardiac disease severity parameters, including LVEF and cardiac history. Nevertheless, it is still possible that the association is confounded by disease severity, especially since some symptoms of cardiac anxiety, such as chest pain, might also be symptoms of heart disease. However, most items in the CAQ focus on the impact of cardiac anxiety on affect (anxious), thought (worrying) or behaviour (avoidance and safety-seeking behaviour).

Although the hazard ratios were particularly higher for women, the gender-specific findings should be considered preliminary because of lack of statistical power. Moreover, the gender-effect was opposite to that found for the association between depression and mortality in cardiac patients and two smaller studies with underrepresentation of women did not find gender effects. Therefore, future studies examining anxiety should preferably examine possible interaction effects with gender.

**Clinical implications**

The present findings of a prognostic association with a MACE, independent from cardiac disease severity and depressive symptoms, stress the potential clinical impact of cardiac anxiety. Interestingly, when looking at the CAQ score alone, the explained variance increased in the follow-up model compared with the baseline measurement (4 and 8% respectively), indicating the importance of identifying (persisting) cardiac anxiety symptoms in the months post-myocardial infarction. Diagnosing elevated cardiac anxiety symptoms, and its specific subtypes, can be helpful in developing specific interventions to reduce maintaining or exacerbating factors, such as avoidance of cardiac stimuli and physical exercise. Cognitive–behavioural therapy (CBT) may target anxiety-related avoidance behaviour, which may even result in a better cardiac outcome. General CBT focusing on stress management has been shown to improve cardiac outcome over 8 years post-myocardial infarction. For this reason, cardiac anxiety should be explicitly addressed in cardiac rehabilitation programmes. Whereas there is awareness of general anxiety in cardiac rehabilitation programmes and recent studies have paid attention to specific types of anxiety recognised by the DSM, such as GAD, cardiac anxiety may in fact be relatively unexplored. Outcomes of cardiac rehabilitation programmes might even improve further if physical exercise is used as a behavioural experiment to test out specific cardiac fears patients may have. In conclusion, the findings of the present study indicate the need to evaluate and target cardiac anxiety – in addition to depression and general anxiety – in the future.
