## Notes and News

## The radiocarbon calendar recalibrated

In Richard Burleigh's account of the 8th International Conference on Radiocarbon Dating in our March issue (1973, 54-6) we learned that 'it was agreed that no particular calibration curve or table should be preferentially adopted at present'. Dr V. R. Switsur, of the Radiocarbon Dating Research Laboratory in the University of Cambridge, thought it would be interesting to examine how the two corrections were obtained and to see where and by how much they disagree. We think that our readers will be interested in, and find useful, his results.
During the 8th International Conference on Radiocarbon Dating at Lower Hutt City, New Zealand, two important papers were presented dealing with the calibration of the radiocarbon time scale by means of dendrochronologically dated specimens of Sequoia and Bristlecone Pine. The first was given by Dr Michael and Dr Ralph of the University of Pennsylvania and the second by Dr Damon, Dr Long and Dr Wallick of the University of Arizona.* Since each of these papers was intended to be used as a correction for raw radiocarbon dates, there was disappointment when it was stated that the two corrections did not agree and the Conference could not recommend their exclusive use. Let us then examine how the two corrections were obtained and see where and by how much they disagree.

Each calibration was based on about 600 radiocarbon analyses of dendrochronologically dated wood. A few measurements from the published data were rejected by the application of various

[^0]critera. Chauvenet's criterion, the first to be applied, is known to reject a small number of good but outlying data and so both sets of authors required supplementary criteria for rejection purposes. 286 of the data points were taken from publications of Dr Suess of the La Jolla radiocarbon dating laboratory. These had to be obtained by the inspection of graphs, since Dr Suess has not yet presented his data in explicit tabular form, so they will all be subject to a small error in reading which is probably not more than about twenty years. The remaining information has been published in tables by Pennsylvania, Arizona and Yale radiocarbon dating laboratories.
The two groups of authors derived their corrections differently. Michael and Ralph first set out to reduce the statistical scatter of the raw data by obtaining the 9 -sample floating averages for the whole curve of deviations from the true ages. This produced a second curve which preserved the larger of the kinks and wriggles of the Suess curve. $\dagger$ Next the 9sample means were again averaged for given periods of 50 or 100 years. These figures were then used to derive the correction factors for the chosen periods and were given in the form of a table.

Damon, Long and Wallick calculated the difference between the radiocarbon age and dendrochronological age for each of the 600 odd points on the curve and then calculated 25-year averages of these. By computer, a curve was fitted to these averages with the method of curvilinear regression analysis using orthogonal polynomials. The standard deviation of the interval points about the curve for 250 -year intervals was calculated. A change of variable
$\dagger$ H. E. Suess, 1970. Bristlecone Pine calibration of the radiocarbon time scale 5200 BC to the present, XII Nobel Symposium (Radiocarbon variations and absolute chronology), 303-309.
was introduced so that the deviations could be plotted against radiocarbon age (which is nonlinear) and hence a correction factor was obtained as well as the standard deviation for 250 -year intervals. This deviation is a function of the geomagnetic field intensity since sunspot variations have a larger effect on radiocarbon production rate during periods of low magnetic field intensity compared with periods of high geomagnetic field intensity.
Throughout the discussion of the work on the Bristlecone Pine calibration of the radiocarbon time-scale Dr H. E. Suess has stated that his is the only true calibration and has refused to allow his results to be published on a single chart together with those from other laboratories.* He maintained the stand in New Zealand that nature is not necessarily as simple as we would wish and an attempt to draw a smooth curve amongst the measured points is probably the wrong approach. He believes that the 'kinks' and 'wriggles' are real and do represent rapid changes of atmospheric $\mathrm{C}_{14}$ activity. These idiosyncrasies of the original data are necessarily obscured by the extensive procedures of averaging used by both Michael and Ralph and Damon et al. in obtaining their new correction curves. The curves have the computational advantage, however, that each radiocarbon measurement yields but one calendar age.

In order to investigate the 'non-agreement' of the two correction factors the columns in Table I show the following: The first two columns give the radiocarbon age in terms of $\mathrm{ad} / \mathrm{bc}$ and bp using the $573^{\circ}$ half-life for radiocarbon (in order to convert dates bp provided by the dating laboratory it is necessary to multiply by the factor $\mathrm{r} \cdot \mathrm{O}_{3}$ ). The third and fourth columns give the corrected age in calendar years as given directly by the Arizona correction and as derived from about the mid points of the Pennsylvania correction factor for

[^1][^2]the same BP age. The next column gives the difference, in years, between the two corrections; positive ( + ) if the Arizona correction yields the older age and negative ( - ) if the Pennsylvania correction gives the older age. The final column gives the mean of the two corrected ages.

The numbers in column 5 are plotted in FIG. I and one can immediately see from this the effects of either correction on any individual radiocarbon date. It will be observed that the difference in most cases is comfortingly small and probably within the limits of the standard deviation provided with the radiocarbon date. Only during the radiocarbon time period 3900 to 5500 bp does the difference exceed 100 years, the average difference for the whole of the time covered being only 34 years.

Since these two correction factors are so close, even though based on different methods of averaging it was thought convenient to accept their mean values as the best corrections available at the present state of the art. Accordingly, these are presented for the 50 -year intervals in column 6 and are plotted in Fig. 2. It should be emphasized that the two papers given at the Conference contain full details of the derivation of the correction factors and tables containing a larger number of conversion points.

The conversion factors are based on about 600 individual measurements and it will be many years before a sufficiently greater number of measurements will be made to alter the shape of the deviation curve significantly. Hence there is little likelihood that correction factors that are very different from these given will be derived. There is every probability, however, that the curve will be extended and areas having a low density of measurements so far, will be made more definitive.

Finally, in Table 2, a systematic comparison is made between the ages obtained by the use of the new correction and those calculated by means of the equation found by Wendland and Donley in their exercise of fitting a curve to the tree ring measurements available at that time. $\dagger$ Their equation for the calendar age is:

$$
112+(0.690 \times \mathrm{R})+\left(1.520 \times 10^{-4} \times \mathrm{R}^{2}\right)-\left(1.38 \times 10^{-8} \times \mathrm{R}^{3}\right)
$$

where R is the radiocarbon age ( 5730 half life).
Over most of the time scale the equation predicts marginally older calendar ages than the new correction. The difference only reaches a magnitude of 70 to 100 years in the earlier two millennia, and is probably due to the larger number of data points now available yielding a more accurate result.

In practice, when converting radiocarbon ages to calendar ages, the statistical uncertainties must not be ignored. The uncertainty quoted with the radiocarbon date is squared and added to the square of the uncertainty given in Damon et al for the appropriate time range. The root of this sum is the uncertainty of
the corrected date. As an example take a radiocarbon date of $5894 \pm 110 \mathrm{bp}$
(a) correct to 5730 half life giving 6070
(b) correct by the calibration chart giving 6747
(c) the uncertainty is $\sqrt{110^{2}+77^{2}}$ (77 is from Damon et al.)

$$
\begin{aligned}
& =\sqrt{12100+18029} \\
& =134
\end{aligned}
$$

So the calendar age for this sample is $6747 \pm$ 134 BP or 4797 士 134 BC.
If this correction is carried out in a publication it is essential that the original date and laboratory number are quoted.
