Abstract
The present study investigated the effects of glutamine (GLN) pretreatment on CD4+ T cell polarisation and remote kidney injury in mice with gut-derived polymicrobial sepsis. Mice were randomly assigned to three groups: normal control fed with American Institute of Nutrition (AIN)-93G diet and two sepsis groups provided with either AIN-93G-based diet or identical components, except part of casein was replaced by GLN. Mice were given their respective diets for 2 weeks. Then, mice in the sepsis groups were performed with caecal ligation and puncture and were killed 72 h after the surgery. Blood, spleens and kidneys were collected for further examination. The results showed that sepsis resulted in decreased circulating and splenic total T lymphocyte and CD4+ T cell percentages, whereas IL-4-, and forkhead box p3 (Foxp3)-expressing CD4+ T cells percentages were up-regulated. Compared with the sepsis control group, pretreatment with GLN maintained blood T and CD4+ T cells and reduced percentages of IL-4- and Foxp3-expressing CD4+ T cells. Also, a more pronounced activation and increased anti-apoptotic Bcl-2 gene expression of splenic CD4+ T cells were observed. Concomitant with the decreased plasma IL-6, keratinocyte-derived chemokine (KC) levels, the gene expression of KC, macrophage inflammatory protein-2 and renal injury biomarker kidney injury molecule-1 (Kim-1) were down-regulated when GLN was administered. These findings suggest that antecedent of GLN administration elicit a more balanced blood T helper cell polarisation, sustained T cell populations, prevented splenic CD4+ T cell apoptosis and attenuated kidney injury at late phase of polymicrobial sepsis. GLN may have benefits in subjects at risk of abdominal infection.

Key words: Glutamine; Sepsis; CD4+ T cells; T cell apoptosis; Kidney injury

Sepsis is a syndrome of physiologic, pathologic and biochemical abnormalities, which is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection(1). Traditionally, the immune response after systemic inflammatory response syndrome (SIRS) was considered to shift towards hypoinflammation and immunosuppression called compensatory anti-inflammatory response syndrome (CARS) to balance the hypermetabolic situation(2). Currently, evidence suggests that SIRS and CARS are interdependent during the course of sepsis(3). Both pro- and anti-inflammatory cytokines can be detected simultaneously during sepsis, sepsis-associated acute inflammatory-metabolic stress and multiorgan dysfunction(4). It is the dysregulation of the pro- and anti-inflammatory mediators during sepsis that leads to multiorgan failure(5). T lymphocytes are crucial for effective immune responses against invading pathogens. Sepsis-induced T lymphocyte dysregulation aggravates the inflammatory response and subsequent outcomes(6).

T lymphocytes can be divided into two subsets: CD4+ and CD8+ T cells. CD4+ helper T (Th) cells have diverse effects on the innate immune system while the major function of CD8+ is to kill the infected cells(7). Th cells are classified into Th1, Th2, Th17 and Th22 subsets, characterised by distinct cytokines and effector functions. Regulatory T (Treg) cells are a distinct CD4+ T cell subset that is implicated in suppressing excessive T cell responses and reduces pro-inflammatory mediator production(8). Previous studies found decreased peripheral and splenic lymphocyte numbers and functions during sepsis(9,10). Restoration of the dysregulated T cell subsets is important in attenuating sepsis-induced inflammation and subsequent organ injury(6).

Abbreviations: BUN, blood urea N; CLP, caecal ligation and puncture; Gr, creatinine; Foxp3, forkhead box p3; GLN, glutamine; KC, keratinocyte-derived chemokine; Kim-1, kidney injury molecule-1; MCP-1, monocyte chemoattractant protein-1; MIP-2, macrophage inflammatory protein 2; NC, normal control; PBMC, peripheral blood mononuclear cells; ROR-γt, RAR-related orphan receptor γt; T-bet, T-box expressed in T cells; Th, helper T; Treg, regulatory T.

Glutamine (GLN) is the most abundant free amino acid in the body. It is an important fuel source for rapid proliferating cells, including immune cells. A number of studies demonstrated that GLN modulates inflammatory mediator expression and has benefits during catabolic and stressed conditions. Previous study has demonstrated that dietary GLN suppressed Th1/Th17 associated pro-inflammatory cytokine expression, thus elicited a more balanced Th1/Threg polarisation in acute colitis mice. In a mouse model of lipopolysaccharide-induced lung injury, intragastric GLN administration reduced Th17 percentage and inflammatory cytokine levels in bronchoalveolar lavage fluid. Parenteral GLN administration after sepsis induction was found to reduce the percentage of IL-17-expressing CD4+ T cells and attenuated the dysregulated immune response in sepsis. However, an ex vivo study showed that high-dose GLN did not induce Th1/Th2/Th17 cytokine responses in peripheral blood mononuclear cells (PBMC) obtained from patients with severe sepsis. Also, GLN administration may repress heat shock protein 72 (HSP72) expression of PBMC after lipopolysaccharide exposure and enhance HSP72 proteins after heat shock induction in patients with sepsis. The influence of GLN on T cell regulation and subsequent outcome in sepsis remain inconsistent. Besides, previous researches showed that GLN had beneficial effects on immunomodulatory response during sepsis; GLN was provided shortly before or immediately after sepsis insult. Most study used a single dose of GLN injection to observe the changes of immune reaction within 24 h. Studies investigating the effect of pretreated dietary GLN on T cell regulation at late septic phase are rare. Since the manifestations of remote organ dysfunction may occur several days after the initiation of sepsis, we designed the present study to evaluate GLN pretreatment on the impact of T cell polarisation and the subsequent kidney injury 3 d after sepsis.

Materials and methods

Experimental animals

Five-week-old C57BL/6 male mice were purchased from the National Laboratory Animal Center (NLAC), Taipei, Taiwan. Mice were kept under a temperature- and humidity-controlled condition with a 12 h light–12 h dark cycle and were fed ad libitum in the present study. The study protocol was approved by the Institutional Animal Care and Use Committee of Taipei Medical University (LAC-2017-00388). The care of the laboratory animals was in full compliance with the updated Guide for the Care and Use of Laboratory Animals (National Research Council, 2010).

Study protocols

After 1 week of acclimation, mice weighing 22–25 g were randomly assigned to one normal control (NC, n = 8) group and two groups of sepsis which was induced by caecal ligation and puncture (CLP). CLP is a well-established animal model to mimic bowel perforation with polymicrobial infection in humans. Mice in the NC group and the positive control CLP group (CLP-C, n = 8) received a common semi-purified diet (American Institute of Nutrition (AIN)-93G). The other sepsis group (CLP-G, n = 8) was administrated a GLN-enriched diet that was AIN-93G-based composition, whereas some part of the casein was replaced by GLN, which provided 25 % of total amino acid nitrogen. This dose of GLN was reported to have an immunomodulatory effect in rodents. The two diets were isonitrogenous and similar in energy and nutrient distributions (Table 1). After the mice were fed the respective diets for 2 weeks, CLP was performed to induce sepsis. Briefly, mice were anesthetised with an intraperitoneal injection of Zoletil (25 mg/kg body weight) and Rumpon (10 mg/kg body weight), a 1 cm incision was made in the abdominal wall, and the cecum was exposed. Approximately, 50 % of the cecum was ligated just below the ileo-caecal valve with 3-0 silk (Ethicon, Somerville). The distal cecum was then punctured in two places with a 22-gauge needle to allow a small amount of faecal material to extrude into the peritoneal cavity, after which it was replaced in the abdomen. The abdominal wound was closed in two layers. Post-operative pain was managed with treatment with 100 µl of 0.25 % bupivacaine at the incision site before skin closure. Mice were injected with 75 mg/kg body weight of antibiotic Ertapenem at 6 h and were killed at 72 h after surgery. Body weights were recorded daily during the experimental period. All mice were anesthetised and then euthanised by cardiac puncture. Blood samples were collected in tubes for cytometric analysis of the T lymphocyte subpopulation. Plasma was obtained by centrifuging the whole blood containing heparin. Spleen and kidney were harvested for further analysis.

Measurements of plasma biochemical parameters

Concentrations of IL-6, IL-10, keratinocyte-derived chemokine (KC), TNF-α, monocyte chemoattractant protein-1 (MCP-1) and macrophage inflammatory protein 2 (MIP-2) in plasma samples were quantified using a MILLIPLEX MAP Mouse High Sensitivity T Cell Panel (Millipore). Creatinine (Cr) (Cayman) and blood urea N (BUN) (BioVision) were measured using commercial kits. Procedures followed the manufacturers’ instructions.

**Distribution of T lymphocyte subpopulations in blood**

To assess the distribution of circulating T cell populations, extracellular staining of CD45-PerCP (Biolegend), CD3-FITC (Biolegend), CD4-APC (eBioscience) and CD8-PE (Biolegend) was applied. The antibodies, mentioned earlier, were incubated with 50 μl aliquots of whole blood for 30 min at 4°C. Following lysis of erythrocytes, the remaining portions were washed twice with FACS buffer for further fluorescent detection. Whole-blood aliquots of 100 μl were incubated with CD4-Pacific blue (Biolegend) to determine the phenotypes of helper T lymphocytes in the blood. Another 100 μl aliquot of whole blood was incubated with CD4-Pacific blue and CD25-APC (eBioscience) for 30 min to analyse the Treg cell percentage. Following rupture of erythrocytes, the remaining leukocytes were fixed and permeated for intracellular cytokine staining. The following antibodies were used for intracellular cytokine staining: IL-4-Alexa Fluor® 488 (Biolegend), interferon-γ-APC (BD Biosciences) and IL-17A-PE (Biolegend). For intracellular staining of forkhead box p3 (Foxp3), leukocytes were fixed and permeated with Foxp3 staining buffer (eBioscience) and Foxp3-PE-Cy7 (Biolegend). All fluorescent samples were analysed with a FACS Canto II flow cytometer (BD Biosciences). CD45-positive leukocytes were gated and then T-cell subsets were determined. As for phenotypes of Th cells, lymphocytes were gated according to their size and granularity using light scatter detectors (forward scatter [FSC]/side scatter [SSC]). CD4-positive lymphocytes were considered Th cells. The percentages of Th-associated cytokine-expressing cells among CD4 T lymphocytes were measured. Treg cells were presented as a percentage of CD25Foxp3 cells among CD4+ lymphocytes.

**Distribution of T lymphocyte subpopulations and activation of T lymphocytes in spleen**

Spleens were minced and ground through a 40 μm cell strainer. Spleenocytes were suspended in Roswell Park Memorial Institute (RPMI)-1640 medium and treated with erythrocyte lysis buffer (Biolegend) for 5 min. Using a buffer containing PBS and 0.5% bovine serum albumin (BSA), spleenocytes were washed twice and resuspended in the buffer. CD69 is an activation marker on T lymphocytes. Expression of CD69 on T lymphocytes was measured by flow cytometry. Aliquots (100 μl) of cell suspensions were incubated with CD45-PerCP, CD3-FITC, CD4-APC, CD8-PE and CD69-PE-Cy7 (Biolegend). CD45-positive leukocytes were gated. T-cell subsets were determined and activated T lymphocytes were evaluated by the expression of CD69 on T cell subpopulations.

**CD4+ T cell isolation from spleens**

To prepare single-cell suspensions, spleens were minced and ground through a 40 μm cell strainer and suspended in RPMI-1640 medium. Following treatment with erythrocyte lysis buffer (Biolegend) for 5 min, spleenocytes were washed twice with a buffer containing PBS, pH 7.2, 0.5% BSA and 2 mM EDTA, and resuspended in the buffer. Then, CD4+ T cells were separated from splenocytes using CD4+ T Cell Isolation Kit (Miltenyi Biotec).

**RNA extraction and quantitative RT-PCR of renal tissues and CD4+ T cell of splenocytes**

We applied Trizol reagent (Invitrogen) to extract total RNA from renal tissues and CD4+ T cells isolated from spleen. RNA (2-5 μg) was reverse transcribed using a RevertAid First Strand cDNA Synthesis Kit (Thermo Scientific) with oligo (dT)18 primers, according to standard protocols. A real-time PCR was carried out in optical ninety-six-well plates on an ABI 7300 Real-Time PCR System (Applied Biosystems). Primers used in the present study are listed in online Supplementary Table S1. T-box expressed in T cells (T-bet), RAR-related orphan receptor γt (ROR-γt), GATA-3, Foxp3, Bim and Bcl-2 primers were used in gene analysis of CD4+ T cell isolated from splenocytes. Bim, Bcl-2, IL-1β, IL-6, TNF-α, MIP-2, KC, MCP-1, high mobility group box 1 (HMGB-1) and kidney injury molecule-1 (Kim-1) primers were used in the measurement of gene expression of renal tissues. The expression of each gene was assayed in a total volume of 25 μl containing 1X Maxima SYBR Green/ROX quantitative PCR Master Mix (Thermo Scientific), 200 nM of each primer and 50 ng of cDNA. Amplification was performed according to the thermocycling protocol recommended by the PCR system, with a final dissociation curve analysis. No-template controls and a melting curve analysis were used to confirm the specificity of the real-time PCR. The multiples of change of messenger (mRNA) were calculated by the equation 2^(-ΔΔCt) (ΔCt indicates the difference of threshold cycles between the target gene and internal control (glyceraldehyde 3-phosphate dehydrogenase (GAPDH) or β-actin) and ΔΔCt indicates the difference in ΔCt between the CLP and NC groups).

**Statistical analysis**

All data are shown as the means with their standard errors. All statistical analyses were performed with GraphPad Prism 5 software (GraphPad Software). Differences among the NC and the two sepsis groups were analysed by one-way ANOVA with Tukey’s post hoc test. Expression of genes was normalised by the NC group being considered as 1. The differences of the gene expression between the two sepsis groups were analysed by t test. A P value of <0.05 was considered significantly different.

**Results**

**Body weights**

There were no differences in the initial body weights among the three groups. The sepsis groups had lower body weights after CLP for 72 h. There were no differences in body weights between the CLP-C and CLP-G groups (data not shown).

**Lymphocyte populations in blood**

Sepsis resulted in decreased percentages of T lymphocyte (CD3+ gated CD45+ population) and CD4+ T cells (CD4+ in CD45+ CD3+ cells). The sepsis group with GLN (CLP-G) had higher percentages of T lymphocyte and CD4+ T cells than the sepsis control group (CLP-C) and had no difference from the NC group.
Concerning the subpopulation of the CD4\(^+\) T cells, the percentages of Th1, Th2 and Th17 cells in the CLP-G group were significantly higher than the NC group. Also, the Th2- and Treg cell percentages were higher in the CLP-C group than the NC group at 72 h after CLP. Compared with the CLP-C group, the CLP-G group exhibited a lower Th2 and Treg cells. No differences in Th1 and Th17 cells were observed between the two sepsis groups (Fig. 1).

**Plasma biochemical markers and inflammation-related chemokine concentrations**

Plasma BUN and Cr levels in the septic groups did not differ from the NC group. There were no differences in plasma BUN and Cr levels between the two sepsis groups. Sepsis resulted in elevation of plasma IL-6, KC and MCP-1 levels after CLP. Compared with the CLP-C group, the CLP-G group had significantly lower IL-6 and KC levels at 72 h post CLP. The MCP-1 levels were down-regulated in the CLP-G group, which was comparable with the NC group (Table 2).

**Distribution of T lymphocyte subpopulations and activation of T lymphocytes in spleen**

The percentages of T lymphocyte and CD4\(^+\) T cells were lower, whereas CD8\(^+\) T cell population (CD8\(^+\) in CD45\(^+\)CD3\(^+\) cells) was higher in the CLP-C group than those of the NC group. There was no difference in T lymphocyte and CD8\(^+\) T cell percentages between the NC and the CLP-G groups. When assessing the differences between the two sepsis groups, proportions
of CD4+ and CD69-expressing CD4+ T cells in the CLP-G group were significantly higher than the CLP-C group. In contrast, the percentages of CD8+ and CD69-expressing CD8+ T cells were lower in the CLP-G group than the CLP-C group (Fig. 2).

**Bcl-2 and Bim expression in CD4+ T cells and CD4 transcription factors gene expression in the spleen**

There was no difference in pro-apoptotic Bim gene expression between the two sepsis groups. However, the anti-apoptotic Bcl-2 gene expression and the Bcl-2:Bim ratio were higher in the CLP-G group than the CLP-C group. Messenger RNA levels of transcription factors for Th cells (T-bet, GATA-3, ROR-γt) and Treg cells (Foxp3) were significantly higher in the CLP-G group than those of the CLP-C group (Fig. 2).

**Gene expression levels in the kidneys**

Expression levels of the anti-apoptotic Bcl-2 gene were higher, whereas mRNA expressions of MIP-2, KC and Kim-1 were lower in the CLP-G than those of the CLP-C group. There were no differences in gene expression of Bim, HMGB-1, MCP-1, IL-1β, IL-6 and TNF-α between the two sepsis groups (Fig. 4).

**Discussion**

In the present study, dietary GLN was administered for 2 weeks prior to induction of sepsis and was continued till the 3rd day after CLP. This model mimics the preventive use of oral GLN in the nutrition regimen to the abdominal surgical patients during the period of hospital stay who may at risk of sepsis after surgery (such as pancreateoduodenectomy, gastrectomy, colectomy, etc.). Antibiotic was used in the sepsis mice after the operation (such as pancreatoduodenectomy, gastrectomy, colectomy, etc.). Antibiotic therapy reverses sepsis-induced T lymphocyte and CD4+ T cell decrement and promote the activation of CD4+ T cell subsets, which may attenuate immune dysregulation and remote kidney injury at late phase of sepsis.

A previous study found that naïve T cell activation and their responses were adversely affected during sepsis. A significant decline of CD4+ T cell numbers in spleen and peripheral blood at 72 h post CLP were reported. Consistent with the studies mentioned earlier, we also found that the percentages of circulating and splenic T lymphocytes and CD4+ T cells decreased. On the other hand, our findings showed that the IL-4-producing CD4+ T cells and Treg were up-regulated in the CLP-G group and were up-regulated in the CLP-C (positive control) group. IL-4 is a cytokine produced by Th2, whereas interferon-γ is produced by Th1 lymphocytes. Th1 cytokines enhance cellular immunity and Th2 enhance humoral immunity. Th1 and Th2 response are counter-regulatory. Previous studies have indicated that a shift from Th1 towards Th2 type response occurs during sepsis. Consequently, marked suppression of cellular immunity makes the host more susceptible to infection and increased mortality. Foxp3 is a transcription factor which is responsible for the development and function of Treg cells. Since the work of Treg cell counteracts the activation of effector Th cell and restrains excessive inflammation, overexpression of Treg may result in immune suppression at late phase of sepsis. Excessive Treg expression was found to increase mortality in the animal model of sepsis. Although one clinical study showed progressive decline of CD14/HLA-DR expression on circulating macrophages but not the number of Treg cells in patients with severe sepsis as compared with healthy control subjects, another study showed increased frequency of Treg cells in septic patients. In the present study, we found that the inflammatory mediators, including...

IL-6, KC and MCP-1, increased in CLP-C groups, indicating systemic inflammation and T cell dysregulation occurs during polymicrobial sepsis.

Dietary GLN supplementation before sepsis exerts several favorable effects that were not found in the sepsis group without GLN. First, GLN pretreatment maintained the percentage of T lymphocyte and CD4⁺ T cell population in blood, increased Th1/Th2 ratio and decreased Treg percentage. These findings suggest that a more balanced T cell polarisation was found at late phase of sepsis when pretreated with GLN. An experiment with human PBMC from septic patients revealed that a high dose of GLN could not alter the Th1:Th2 ratio and decreased Treg percentage. These findings suggest that a more balanced T cell polarisation was found at late phase of sepsis when pretreated with GLN. The balance between Bcl-2 and Bim plays a critical role in regulating the homeostasis of T cells. Since the Bcl-2:Bim ratio of the splenic CD4⁺ cells was higher in the CLP-G than the CLP-C, GLN supplementation maintained spleen CD4⁺ T cell population after sepsis may possibly result from preventing the apoptosis of the T cells. Previous study also found that GLN enhanced γδ T cell activation and prevented γδ T cell apoptosis in sepsis. Third, pretreatment with GLN exerted a greater extent of splenic CD4⁺ T cells activation after sepsis. CD69 is a surface antigen expressed by T cells. CD69 expression can be induced after stimulation and persist for at least 3 d to promote T cell activation and proliferation. This may partly explain the up-regulated and maintained Th- and Treg-associated transcription factors gene expression.

Fig. 2. Distribution of T-cell subpopulations and activation of CD4⁺, CD8⁺ T cells in spleen. T cells were determined by CD3⁺ cells in CD45⁺ cells using a flow cytometer. CD4⁺ and CD8⁺ T cells were respectively identified by CD4⁻ and CD8-expressing cells among CD45⁺ CD3⁺ cells. Activated T cells were determined by the expression of CD69 on CD4⁺ or CD8⁺ T cell subsets. NC, normal control group; CLP-C, control group with caecal ligation and puncture (CLP) surgery; CLP-G, glutamine group with CLP operation. Values are means, with their standard errors represented by vertical bars (n = 8 for each group). * Mean value was significantly different from that of the NC group (P < 0.05). † Mean value was significantly different from that of the CLP-C group (P < 0.05).
observed in the CLP-G group. This finding may also indicate that
immunosuppression was not observed in the sepsis group pre-
treated with GLN. Fourth, GLN pretreatment attenuate kidney
injury during sepsis. In the present study, conventional biochemi-
ical markers of renal function, including BUN and Cr, were
analysed and the levels did not rise after CLP. Although these
indicators are frequently used, they are influenced by many
non-renal events and considered non-specific for detection of
renal injury(34,35). Kim-1 is a transmembrane protein expressed
on tubule epithelial cells. It is considered as a novel biomarker
for acute renal injury(36). In the present study, we found that
Kim-1 expression in the GLN sepsis group was down-regulated.
Also, the gene expression of inflammatory mediators MIP-2 and
KC decreased while anti-apoptotic Bcl-2 gene increased signifi-
cantly when the sepsis group was pretreated with GLN. MIP-2
is a major CXC chemokine involved in the migration of neutrophil
to sites of inflammation(37). KC is a CXC chemokine that play an
important role in mediating neutrophil recruitment(38). These find-
ings indicated that prophylactic administration of GLN prevented
apoptosis and alleviated inflammation that may consequently
attenuate kidney injury at late phase of sepsis.

A multicenter clinical trial reported that GLN supplementation
had no benefits in clinical outcome and even harmful when
given to critical patients with multiorgan failure(39). Previous
study also found that early immune-enhancing nutrition supple-
mented with GLN, arginine and antioxidants may modulate cyto-
kine production, but had no impact on outcome in children with
septic shock(40). Furthermore, a review article reported that GLN
supplementation does not reduce mortality or late-onset sepsis
in early life and is not recommended for immune-competent
patients(41). Since impairment of GLN utilisation occurs in organ

ificantly different from that of the CLP-C group (P < 0.05).
dysfunction, the outcomes mentioned earlier may not apply to different septic situation. A systemic review reported that GLN supplementation reduces mortality and hospital stay in septic patients following resolution of multiorgan failure. GLN is a precursor for the endogenous antioxidant glutathione (GSH). Previous studies demonstrated that GLN promoted T cell proliferation and decreased T cell apoptosis possibly through GLN-GSH axis and the redox capacity. GLN pretreatment may provide sufficient fuel source to fulfill metabolic needs and regulate the T cell homeostasis that may consequently result in a more balanced T cell subsets and alleviate inflammation after sepsis. However, the mechanisms responsible for the effects of GLN on regulating T cell polarisation requires further investigation.

In summary, the present study demonstrated that GLN administration before sepsis maintained the percentage of T lymphocyte and CD4+ T cell population in blood, activated and prevented apoptosis of splenic CD4+ T cell and elicited a more balanced systemic CD4+ T cell polarisation. Also, antecedent administration of GLN attenuated inflammation and kidney injury at late phase of sepsis. These findings imply that GLN use may have beneficial effects in patients of abdominal infection risk.
