Beamswitching has been used at 10, 15 and 33 GHz to map the microwave background over the Declination range 30° to 45°, covering more than one steradian of the sky. The beamwidth is 5° and the beam-throw is ±8° at each frequency. The three data sets are used to separate Galactic emission from intrinsic CMB emission. For the scan at Dec = 40° the intrinsic fluctuation level is $\Delta T_{\text{rms}} = 48^{+21}_{-15} \mu$K on a coherence scale of 4°; the equivalent analysis for a Harrison-Zeldovich model gives a power spectrum normalisation of $Q_{\text{rms}} = 22^{+10}_{-6} \mu$K. The value of the fluctuation amplitude calculated from the likelihood analysis of the two-dimensional data set is $\Delta T_{\text{rms}} = 54 \pm 13 \mu$K at 10 GHz and $39^{+8}_{-7} \mu$K at 15 GHz.

A short baseline interferometer has been operating at 33 GHz. The spacing of the two low-spillover horns is $17\lambda$ (152 mm). The bandwidth is 3 GHz giving an rms noise of 200 $\mu$K in 2 minutes. With a primary beamwidth of $5° \times 2.5°$ the interferometer lobe size is $1.7° \times 2.5°$. The interferometer is largely unaffected by atmospheric water vapour. Data at Dec = 41° show significant structure at high signal-to-noise. The section from RA = 08-19 hr shows CMB structure at an rms level of $\sim 20 \mu$K; this corresponds to a sky $\Delta T_{\text{rms}} \sim 100 \mu$K, at an angular scale of 2°, when corrected for dilution; a value significantly larger than found in our beamswitching experiments on a $5° - 15°$ angular scale. This work is now being extended in the Very Small Array, Tenerife, a collaboration between our three groups. This has 14 antennas operating at baselines up to 2 m in the frequency range 26–36 GHz. The sensitivity will be $\Delta T/T \sim 2 \times 10^{-6}$ in several months, in the range $l = 100 - 1000$. Observations will begin in 1999.
