Abstract

The aim of the present study was to assess the long-term effects of a high-energy-dense diet, supplemented with Lactobacillus plantarum (Lp) or Escherichia coli (Ec), on weight gain, fattening and the gut microbiota in rats. Since the mother’s dietary habits can influence offspring physiology, dietary regimens started with the dams at pregnancy and throughout lactation and continued with the offspring for 6 months. The weight gain of group Lp was lower than that of groups C (control) and Ec (P = 0.086). More retroperitoneal adipose tissue (P = 0.030) and higher plasma leptin (P = 0.035) were observed in group Ec compared with group Lp. The viable count of Enterobacteriaceae was higher in group Ec than in group Lp (P = 0.019), and when all animals were compared, Enterobacteriaceae correlated positively with body weight (r = 0.428, P = 0.029). Bacterial diversity was lower in group Ec than in groups C (P ≤ 0.05) and Lp (P ≤ 0.05). Firmicutes, Bacteroidetes and Verrucomicrobia dominated in all groups, but Bacteroidetes were more prevalent in group C than in groups Lp (P = 0.036) and Ec (P = 0.056). The same five bacterial families dominated the microbiota of groups Ec and C, and four of these were also present in group Lp. The other five families dominating in group Lp were not found in any of the other groups. Multivariate data analysis pointed in the same directions as the univariate statistics. The present results suggest that supplementation of L. plantarum or E. coli can have long-term effects on the composition of the intestinal microbiota, as well as on weight gain and fattening.

Key words: Body weight; Probiotics; Biochemical markers; Gut microbiota; High-energy-dense diet

Although the primary reason for obesity is energy intake exceeding energy expenditure, it is becoming increasingly clear that overweight can also be associated with individual differences in energy extraction capacity, genetic background and gut microbiota (1–5). While intestinal microbes contribute to colonisation resistance, nutrition, and the development and tuning of the immune system (6), studies in both human subjects and animals have also shown a connection between the gut microbiota and obesity (1–5).

Antibiotic treatment is known to manipulate the intestinal microbiota. In experimental studies, it has been postulated that antibiotic treatment during pregnancy impairs the physiology and intestinal microbiota of rat pups (6), and antibiotic modulation of mouse gut microbiota has been shown to change the metabolic status of the host (5).

Since the sterile fetus is colonised by micro-organisms from the mother and the surrounding environment at birth, it can be hypothesised that the microbial heritage from the mother can be important for offspring development and health. Furthermore, the microbiota of the mother can be affected by dietary factors. For example, a high intake of fat can affect the gut microbiota (5).

Constant exposure to bacteria through diet may well have effects in the long run. In the present study, the two non-pathogenic bacteria Lactobacillus plantarum DSM 15313, designated in the division Firmicutes (family Lactobacillaceae), and Escherichia coli CCUG 29300T (T = type strain), designated

Abbreviations: C, control; Ec, Escherichia coli CCUG 29300T; HEDD, high-energy-dense diet; Lp, Lactobacillus plantarum DSM 15313; LPS, lipopolysaccharide; T-RF, terminal restriction fragment; T-RFLP, terminal restriction fragment length polymorphism.

in the division Proteobacteria (family Enterobacteriaceae),
were given to rat dams and their offspring. L. plantarum
frequently occurs spontaneously and in high numbers in most
lactic acid-fermented foods, especially those based on plant
material, for example, brined olives, capers, sauerkraut, salted
gherkins, cassava, and in grape juice and wine. However,
L. plantarum is also present in the human intestinal
mucosa, and probiotic effects of certain strains of this species
have been documented in human subjects, for example, reduction in abdominal bloating and pain in patients with
the irritable bowel syndrome and reduction in CVD risk factors. Furthermore, administration of L. plantarum to
pregnant dams has been shown to stimulate gut growth and
development in their suckling offspring. The particular
strain, L. plantarum DSM 15313, used in the present study has
been shown to mitigate colitis, translocation and liver injury in
rats. Refrigerated foods such as milk, meat and vegetables
in an early phase of deterioration, before loss of apparent edibility,
expose the consumer to different types of bacteria. Those
bacteria are typically Gram-negative Proteobacteria such as
Pseudomonas and Enterobacteriaceae that have pro-
flammatory lipopolysaccharides (LPS) associated with their
cell membranes. E. coli is a Gram-negative commensal in
the gastrointestinal tract. Non-pathogenic strains of E. coli can
also exert inflammatory stimuli by their LPS, and changed
cecal microbiota, as well as increased inflammatory level,
have been observed in rat pups with mothers receiving E. coli
during pregnancy and lactation. It has been shown in mice
that LPS in the blood (endotoxaemia) is a starting point for

### Experimental methods

#### Study design and animals

For each study group, three adult female Sprague–Dawley
rats (Taconic, Ry, Denmark) of similar weight and age were
mated with different male rats. From 2 weeks before parturi-
tion, dams were housed individually and were assigned diet
and bacterial supplements at that time as described below.
At weaning, about 4 weeks of age, nine of the female off-
spring from each study group were randomly mixed into
cages with three animals in each cage. They continued
in the experiment for 6 months. Throughout the experiment,
animals were housed in polycarbonate cages on chopped
aspen wood bedding (Beekay bedding; Scanbur BK AB,
Sollentuna, Sweden), and the experiment was run in a control-
ed environment (21 ± 1°C and 50 ± 10% relative humidity;
12 h light–12 h dark cycle). The experiment was conducted
in compliance with all relevant Swedish laws and institutional
guidelines, and the Regional Ethical Review Board, Lund,
Sweden, approved the study (approval no. M16-07).

#### Diets, bacterial supplement and body-weight recordings

The purified HEDD with 41% of energy as fat, 41% of energy
as carbohydrates, of which half was sucrose, and 18% of
energy as protein was produced by Research Diets (New
Brunswick, NJ, USA; see Table S1 of the supplementary
material, available online at http://www.journals.cambridge.
org/bjn). Feed was administered ad libitum, and the con-
sumption per cage was recorded once a week. In addition
to the HEDD, one group received Lactobacillus plantarum
DSM 15313 suspended in freezing medium (4.28 mM-
K2HPO4, 1.31 mM-KH2PO4, 1.82 mM-sodium citrate, 0.87 mM-
MgSO4·7H2O and 1.48 mM of 98% glycerol) (Lp), while
another group was given Escherichia coli CCUG 29907
suspended in the freezing medium (Ec) in their drinking-
water. The control (C) group received a corresponding
amount of freezing medium in their water. The treatment
to dams began during the last two-thirds of pregnancy and
continued during lactation. The offspring were then given
the same treatment as their mothers until 6 months of age.

A frozen high-density preparation of L. plantarum DSM
15313, originating from the intestine of a healthy human indivi-
dual, was provided by Probi AB (Lund, Sweden). E. coli
CCUG 29907, a non-pathogenic strain of human origin, was
grown in brain heart infusion medium (Oxoid, Basingstoke,
Hampshire, UK) in a shaking water-bath at 36°C for 16 h.
The cells were stored in freezing medium after harvesting.
All bacteria were kept at −80°C until feeding. The bacterial
suspension was poured into the drinking-water on the day of
administration. Water was changed, and consumption was
recorded daily. Confirmed by culturing, viable counts
of E. coli and L. plantarum were stable during 24 h in
tap water at room temperature. Each cage was given 106
colon-forming units/d of L. plantarum or E. coli in 200 ml
water. Every rat consumed approximately 106 colony-forming
units/d of L. plantarum or E. coli. The birth weight of the litter
(all pups taken together) was recorded the day after delivery,
and a mean birth weight of each animal was assigned. Body weight was measured weekly from weaning until killing.

**Procedure at animal killing and blood and organ sampling**

At 6 months of age, non-fasted animals were anaesthetised by subcutaneous injection of 0.375 mg flunisolone and 0.012 mg fentanyl citrate/100 g body weight (Hypnorm® VetPharma Limited, Leeds, Yorkshire, UK) and 0.188 mg midazolam/100 g body weight (Dormicum®, Roche, Basel, Switzerland).

Under aseptic conditions, a laparotomy was performed through a midline incision. Blood from the aorta was sampled into ice-chilled endotoxin-free polystyrene tubes (Lonza, Copenhagen, Denmark) containing EDTA as an anticoagulant to obtain plasma. Blood was also collected in BD Vacutainer tubes (Becton Dickinson, Plymouth, Devon, UK) to obtain serum. Plasma and serum were stored at −80°C until further analyses. Plasma for the determination of endotoxin was stored in endotoxin-free tubes (Biopur 1.5 ml tubes; Eppendorf, Hamburg, Germany). Left retroperitoneal and periovarial adipose tissue, spleen and adrenals were carefully dissected and weighed. Caecal and rectal content and liver tissue were frozen, in freezing medium for culturing, in liquid N₂, and stored at −80°C until analyses.

**Biochemical analyses**

Plasma leptin was analysed using ELISA (Crystal Chem, Inc., Downers Grove, IL, USA), with the detection limit of 0.2 ng/ml. Plasma haptoglobin was analysed colorimetrically, with an assay sensitivity of 0.05 mg/ml (Phase™ Range Haptoglobin Assay; Tridelta Development Limited, Kildare, Republic of Ireland), according to the manufacturer’s instructions. Plasma endotoxin was determined by an accredited chromogenic endpoint method based on limulus amebocyte extract (Charles River Laboratories, Charleston, SC, USA). Samples were diluted 1:10 and heated at 75°C for 10 min; the detection limit was 0.031 U/ml. Each sample was spiked with endotoxin, and 50% recovery was ensured in order to analyse lack of inhibitors and verify reliability. Serum bilirubin, aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase were analysed colorimetrically, and rectal content of calprotectin was analysed using ELISA (Immundiagnostic AG, Bensheim, Germany).

**Liver histology**

Liver tissue was fixed in 4% buffered formaldehyde (Histolab, Göteborg, Sweden), rinsed in water and dehydrated in graded ethanol concentrations, followed by xylene and embedded in paraffin. Sections (5 μm) were mounted on slides, deparaffinised and stained with haematoxylin and eosin, and the prevalence of steatosis was scored as follows: 0, no visible steatosis; 1, steatosis in <1/3 of the hepatocytes; 2, steatosis in 1/3–2/3 of the hepatocytes; 3, steatosis in >2/3 of the hepatocytes. The histological evaluation was performed by a blinded scientist.

**Microbial analyses**

In order to analyse the amount of viable lactobacilli and *Enterobacteriaceae* in the caecum, a conventional dilution series was performed, and samples from appropriate dilutions were plated on Rogosa agar (Oxoid) and violet red bile dextrose agar (Oxoid) and incubated at 37°C for 72 h anaerobically and 24 h aerobically, respectively. Translocation of viable bacteria was evaluated by anaerobic and aerobic cultivation of liver tissue on the brain heart infusion agar (Oxoid) at 37°C for 72 h. Microbial diversity was assessed by the terminal restriction fragment length polymorphism (T-RFLP) method, and cloning and sequencing were used to imply phylogenetic affiliations of the intestinal microbiota. The procedures are described in the supplementary material (available online at http://www.journals.cambridge.org/bjn).

**Calculations**

The relative abundance of each terminal restriction fragment (T-RF) within a given T-RFLP pattern was calculated as the peak area of the respective T-RF divided by the total peak area of all T-RF, in the given T-RFLP pattern, detected within a fragment length of 20–600 bp. Relative abundance was used for calculations of diversity index. Shannon and Weaver (Shannon, *H’*) and Simpson (*D*) indices were calculated for all individuals by using the equations:

\[
H’ = - \sum p_i \ln p_i \quad \text{and} \quad 1 - D_i
\]

where \(D = \sum p_i^2\) and \(p_i\) is the relative abundance of the \(i\)th peak in the community \((22)\). T-RF incidences were calculated using Fisher’s exact test, and two-tailed \(P\) values were reported.

Statistical evaluation was performed using the Kruskal–Wallis test followed by the Nemenyi–Damico–Wolfe–Dunn test \((23)\) using the package coin \((24)\) in the statistical software R 2.9.1 (The R Foundation for Statistical Computing, Vienna, Austria). Spearman rank order correlation coefficients were calculated using SigmaStat 3.1 (Systat Software, Point Richmond, CA, USA), and Fisher’s exact test was performed with Statistics Online Computational Resource (http://www.socr.ucla.edu/SOCR.html). A \(P\) value of <0.05 was considered significant.

Multivariate data analysis with orthogonal partial least squares to latent structures discriminant analysis was performed using SIMCA-P+ 12.0.1 (Umetrics, Umeå, Sweden) to reveal differences between the treatment groups \((25, 26)\).

**Results**

**Animal health and performance**

All animals (nine animals per group) appeared healthy throughout the study, with the exception of one rat in group Ec that was killed after 12 weeks after veterinarian consultation and recommendation, due to the finding of a subcutaneous tumour. Data from this rat were excluded. Of the remaining Ec rats, one was perceptibly leaner than the others, as confirmed at dissection at the end of the study.
Effects on body and organ weights

Pups in group Lp had the lowest (7·47 g) and group Ec had the highest (9·65 g) mean birth weight, while group C had an intermediate birth weight (8·15 g). However, because of the limited number of litters, statistical analysis could not be performed. Group Lp had lower body weight throughout the study compared with groups C and Ec, and at 6 months; the difference was more prevalent in the Ec library than in the C library (Fig. 2). As regards proportions of the microbiota, significantly more retroperitoneal fat was observed in group Ec compared with group Lp (P=0·03; Table 1). The weight of retroperitoneal fat correlated positively with body weight after 6 months (r=0·45, P=0·002). Group Ec had a higher median weight of the periovarial fat deposit compared with the other groups, but the difference was not significant (Table 1). The weight of spleen was higher in group Ec than in group Lp (P=0·006; Table 1). Group Lp had heavier adrenals than group C (P=0·022; Table 1).

Effects on liver histology

The incidence of liver steatosis was significantly lower in group Ec compared with that in group C (P=0·008; Table 1).

Effects on biochemical markers

Group Ec showed significantly higher plasma leptin concentrations than group Lp (P=0·035; Table 2). Haptoglobin was significantly lower in group Ec compared with group C (P=0·003; Table 2), but no significant differences were observed in the blood levels of endotoxin, bilirubin or the liver enzymes aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase, nor in intestinal calprotectin (Table 2). However, group C had the highest aspartate aminotransferase concentration, which approached statistical significance (P=0·087).

Effects on microbiota

Significantly lower bacterial diversity was observed in the caecum of group Ec compared with that in group C when diversity indices were calculated for the T-RFLP profiles (Table 3). When Msp1 was used for DNA digestion, group Ec had significantly lower diversity than group Lp (Table 3). Clone libraries from the different groups showed that divisions *Firmicutes*, *Bacteroidetes* and *Verrucomicrobia* were represented in all three groups at a level ranging 65–77, 4–26 and 5–15 %, respectively. At the hierarchical level of family, the same five taxa dominated the microbiota in animals with the most diverse microbiota (according to T-RFLP profiles) in groups C and Ec, while nine taxa were seen in group Lp (Fig. 2). As regards proportions of the microbiota, significant differences were observed between the treatment groups at division level. Members of the *Bacteroidetes* were less prevalent in the Ec library than in the C library (LibCompare in Ribosomal Database Project, P=0·036) and

were close to significance for less prevalence in the Lp library compared with the C library (P=0·056). No significance in proportions of sequences belonging to *Firmicutes* was observed. All sequences of *Verrucomicrobia*, independent of the treatment group, corresponded to *Akkermansia muciniphila*. *Incertae sedis XIII* included sequences most similar to those of *Anaerovorax odorimutans* but with a low similarity score (0·94). Incidence of T-RF differed significantly between groups Lp and C, and between groups Ec and C (see Table S2 of the supplementary material, available online at http://www.journals.cambridge.org/bjn). The gut microbiota was also significantly different in groups Lp and Ec, since group Ec, with *AluI* digestion, had the highest incidence of T-RF at 77 bp and the lowest incidence of 203 bp. With *MspI* digestion, the T-RF at 257 bp was higher, and T-RF of 80, 258 and 516 bp was found at significantly lower incidence in group Ec than in group Lp.

The viable count of *Enterobacteriaceae* in the caecal content was significantly higher in group Ec compared with that in group Lp (P=0·019; Table 3) and correlated positively with body weight after 6 months (r 0·428, P=0·029). No significant differences were observed in the lacticobacilli count of caecal content or the translocation of viable bacteria to the liver.

### Multivariate analysis

Results of multivariate data analysis with orthogonal partial least squares to latent structure discriminant analysis depict a substantial difference between the different groups. Important for the separation of groups Lp and Ec were fat deposition, viable count of *Enterobacteriaceae* and microbial diversity (Fig. 3). Significant for the separation of groups Ec and C were fat deposition and diversity indices, while separation of groups Lp and C were based on body weight and weight of adrenals, Q2 0·79 and 0·58, respectively.

### Discussion

Feeding with an HEDD and the two bacterial supplements was initiated during pregnancy, because it is known that metabolic malprogramming in the offspring can occur when the dietary intake of the pregnant dam is manipulated(27,28). In the present study, *E. coli* was chosen as one supplement, since it has been shown that this Gram-negative bacterium, with pro-inflammatory LPS associated with its cell wall, can occasionally dominate the intestinal microbiota in human infants(29). *E. coli* was also observed to dominate in the sigmoidal mucosa in one out of nine 60-year-old volunteers.

C, control; Lp, *Lactobacillus plantarum* DSM 15313; Ec, *Escherichia coli* CCUG 29300<sup>T</sup>; AST, aspartate aminotransferase; ALT, alanine aminotransferase; ALP, alkaline phosphatase.

<sup>a,b</sup> Median values within a row with unlike superscript letters were significantly different (P≤0·05).
without clinical symptoms or medication when sequence analysis of cloned 16S rRNA genes, as enriched by PCR from biopsies, was applied (91% of the clone library were related to E. coli; G Molin, unpublished results). In contrast, L. plantarum was selected since it is a Gram-positive commensal of the gastrointestinal tract and can confer health benefits as probiotics[10,11].

In the present 6-month study, long-term bacterial supplementation seemed to affect the weight development of the rats, without having any effect on the feed consumption. Furthermore, when repeated-measures ANOVA was calculated, group Lp had significantly lower body weight compared with group C (data not shown). Importantly, L. plantarum decreased body-weight gain, and E. coli increased body fat, the latter being consistent with the hypothesis of Cani et al. (5) which suggests increased body-weight gain by high-fat feeding and an increased load of Gram-negative bacteria. To our knowledge, effects of probiotics on weight gain have not previously been experimentally evaluated from fetal life to adulthood. However, Lactobacillus gasseri SBT2055 has been shown to significantly reduce abdominal visceral and subcutaneous fat[30], and lower BMI has been suggested in children after Lactobacillus rhamnosus GG administration[31].

Intestinal diversity has previously been shown to increase in rodents receiving probiotics[32,33]. However, these findings were from short-term studies, in which no physiological parameters were evaluated. Thus, there is a general lack of knowledge regarding the long-term effects of bacterial supplements on intestinal microbial diversity in combination with changed homeostasis. Calculation of diversity index is a common way to estimate microbial diversity[18,20–22], and low diversity has been associated with various diseases[18–20].

In the present study, reduced bacterial diversity indices were observed in group Ec compared with group C. Group Ec had a significantly increased viable count of Enterobacteriaceae in the caecal compared with group Lp, as well as lower diversity indices, thereby indicating that E. coli consumption might associate with a tendency of overgrowth of unfavourable bacterial groups. Furthermore, the amount of Enterobacteriaceae in the caecal content was positively correlated with body weight. The incidence of specific T-RF varied among the groups, which further supports the observation of different intestinal microbiota according to treatment.

Previous reports have suggested a reduction in the abundance of Bacteroidetes and a proportional increase in Firmicutes in obese individuals[2,3]. However, this was not the case in the present study as both the groups of the heavier Ec animals and the leaner Lp animals had lower proportions of Bacteroidetes compared with group C. Furthermore, the proportion of Firmicutes did not vary between the groups. This suggests that the microbiota must be dealt with on lower hierarchical levels than that of division, preferably on the species level but at least at family and genus levels. It also seems important to look into different experimental models with different strains and species of animals, and also different categories of human subjects. Hence, more extensive studies are required to fully explain the connection between gut microbiota and obesity.

In an attempt to evaluate the correlation of intestinal microbiota and changed homeostasis, we measured various biochemical markers. Previously, adult offspring to LPS-exposed dams have been reported to have higher body weight, heavier fat deposits and higher serum leptin[34]. The same scenario was true in the present study for the group where the mothers and the offspring received E. coli. Interestingly, the opposite effect was observed in the group receiving L. plantarum: lower leptin levels were observed in combination with lower body weight.

The acute-phase protein haptoglobin, mainly produced by the liver[35], is known to increase during inflammation, but contradictory results have also been reported[36,37]. Since obesity is characterised by low-grade inflammation[5,38] and group Ec in the present study had more body fat and higher leptin levels, the animals in this group were assumed to have a higher inflammatory tone. In spite of this, group Ec had significantly lower haptoglobin concentrations compared with group C. Interestingly, one of the primary
functions of haptoglobin is to restrict Fe availability to pathogenic bacteria by the formation of an irreversible complex with Hb released from damaged erythrocytes\(^\text{39,40}\). The decreased haptoglobin concentration found in group Ec might be a result of even non-pathogenic \textit{E. coli} strains being equipped with efficient means (siderophores) to absorb Fe\(^\text{41}\). In the present study, significantly heavier spleens were found in group Ec compared with group Lp, indicating systemic inflammation in group Ec\(^\text{42}\). Furthermore, intravascular haemolysis is associated with splenomegaly and decreased haptoglobin levels\(^\text{43}\).

Esposito \textit{et al}\(^\text{44}\) reported reduced liver damage and inflammation in young rats on a high-fat diet when this was combined with the probiotic mixture VSL\#3 containing different strains of \textit{Lactobacillus} and \textit{Bifidobacterium}, but no microbial evaluation was performed. In the present study, no statistically significant changes in liver enzymes were observed. However, aspartate aminotransferase and haptoglobin concentrations were highest in group C, which is in accordance with the higher occurrence of liver steatosis in this group. Non-pathogenic strains of \textit{E. coli} have indicated improvement of liver function, while other \textit{Enterobacteriaceae} showed the opposite\(^\text{45}\). This highlights the potential to influence the level of steatosis and liver function by modulating the intestinal microbiota. Notably, in the present study, eating behaviour was not controlled before blood sampling at killing, and, for example, plasma LPS is enhanced after a meal\(^\text{46}\), thus some measurements may be on the small side.

It should be stressed that in the present study, calprotectin in the intestinal content did not vary between the

groups, suggesting absence of intestinal inflammation. Hence, although systemic effects were observed, neither E. coli nor L. plantarum seemed to have injured the gastrointestinal tract.

The weight of adrenals was significantly higher in group Lp than in group C, but it was not possible to distinguish the weights of the medulla and cortex, making it hard to evaluate the consequences and underlying relevance of the difference in the weight of this organ.

Although not totally conclusive, the present results indicate that it may be possible to affect host homeostasis by bacterial supplementation to rats consuming an HEDD. In future studies, larger study populations should be used, and physiological and microbial characterisation of rat dams should be addressed more extensively. Furthermore, extensive evaluation of the offspring early in life should be performed to distinguish the effect obtained on the fetus in utero, during the neonatal and weaning periods. Litter sizes and social behaviour, such as cage hierarchy, should also be considered.

In summary, the long-term effects of bacterial supplements to HEDD-fed rats were studied from fetal life to adulthood in outbred rats. Animals receiving L. plantarum had lower body weight, less retroperitoneal adipose tissue and lower plasma leptin compared with those that were given E. coli. The diversity of the intestinal microbiota was reduced in rats consuming E. coli, which highlights the potential of modulating intestinal microbiota and homeostasis. As shown by the multivariate analysis, fat deposition and weight gain were affected by the gut microbiota, and manipulated by the supplementation of bacteria to an HEDD.

Acknowledgements

Mrs Camilla Björklöv is thanked for her assistance with the animal care and Mrs Susanne Eiwold for embedding of the liver tissues. Dr Fredrik Nilsson at the Competence Centre for Clinical Research, Region Skåne (Lund, Sweden), is greatly acknowledged for his statistical recommendations and calculations in R, and Martin Berntsson at Umetrics (Umeå, Sweden), for his guidance in multivariate evaluation of the results. The present study was supported by grant from the Swedish Research Council Formas (grant no. 222-2007-501). G. M., B. J. and S. A. are minority shareholders in Probi AB (Lund, Sweden), and the authors’ relationship between the company and their positions at the university has been regulated by an agreement between Lund University (Lund, Sweden) and Probi AB (Lund, Sweden). C. L. J. K., F. F., M.-L. J. H., M. J., Å. H. and B. W. disclose no conflicts of interest. C. L. J. K., G. M., F. F., M. J., Å. H., B. J., B. W. and S. A. designed the study; C. L. J. K., F. F., M. J. and A. H. collected the data; C. L. J. K., G. M., M.-L. J. H. and S. A. analysed and interpreted the data; C. L. J. K., G. M. and S. A. wrote the manuscript; all authors read and approved the final version of the manuscript.
