(Received 31 July 2001 – Revised 5 December 2001 – Accepted 13 January 2002)

The present study tested the hypothesis that habitual exercisers demonstrate an increased accuracy of regulation of food intake in compensation for previous dietary energy intake. Twenty-three lean healthy male subjects were divided into two groups on the basis of their habitual exercise levels: non-exercisers (no exercise sessions/week,  $n$  9), and exercisers ( $>$  two exercise sessions of 40 min or more/week,  $n$  14). The appetite response to covert liquid preloads of high (2513 kJ) energy (HE) and low (1008 kJ) energy (LE) was investigated Sixty minutes after the preload subjects were offered an *ab libitum* buffet-style meal and energy intake (EI) was calculated. Subjective hunger and satiety were assessed throughout using self-rated visual-analogue scales. Buffet EI in non-exercisers was not significantly different following the LE or HE preloads (mean compensation 7%), but the exercise group significantly reduced their energy intake following the HE, compared with the LE, preload (mean compensation 90%;  $P=0.0035$ ). A broadly similar pattern of response was observed for both moderate (two to three sessions/week,  $n$  7) and high exercisers ( $>$  four sessions/week,  $n$  7). There were no significant differences between hunger or satiety ratings following HE or LE preloads for either group. However non-exercisers scored significantly higher on their self-ratings of hunger at the start of the study, before preload consumption, compared with the exercisers ( $P<0.01$ ). These findings demonstrate that habitual exercisers have an increased accuracy of short-term regulation of food intake in compensation for preload manipulation, and provide additional support for advocating regular exercise in the prevention of overweight and obesity.

### Exercise: Appetite: Food intake: Satiety

The role of exercise in the prevention of positive energy balance and obesity is well-recognised (King, 1999; Moore, 2000). Increases in physical activity are strongly correlated to lower levels of obesity (Lean, 2000) and regular exercise has been related to the success of weight (Fogelholm *et al.* 2000) or fat-mass maintenance (Pasman *et al.* 1999) after a low-energy diet. However, the mechanisms by which exercise may act to beneficially affect energy balance are not clear. In terms of the relationship between energy deficit and energy intake *per se*, short-term feeding studies using the manipulation of preload energy content to alter energy balance have demonstrated differences in hunger and subsequent food intake following high- and low-energy preloads (Pliner, 1973; Lawton *et al.* 1993; Green *et al.* 1994). Appetite responses are thus dependent to some extent upon previous energy intake and sensitive to energy deficits induced through differences

in intake. However, in contrast, energy deficits induced through increases in exercise do not generally result in short-term increases in hunger ratings or in an elevated energy intake (King *et al.* 1997a; Blundell & King, 1998), and athletes in situations that require sustained performance, such as the Tour de France cycle race, have to learn in respect to food intake in order to prevent negative energy balance (Westerterp-Plantenga, 1999); in addition, becoming sedentary does not down-regulate food intake (Murgatroyd *et al.* 1999). This uncoupling between energy intake and energy expenditure when energy expenditure is manipulated by exercise has been reported to persist for several weeks in obese individuals (Woo *et al.* 1982a, b); it has also been reported to occur to a lesser extent when energy expenditure is manipulated by diet (Westerterp-Plantenga *et al.* 1999).

However, in contrast to the weak coupling between

energy intake and expenditure in the short term, physically active individuals who habitually exercise, such as runners, have been shown to have suitably high-energy intakes (Maughan *et al.* 1989), suggesting a positive relationship between long-term physical activity and food intake for the maintenance of body weight. If athletes and other individuals habituated to higher levels of energy expenditure show better coupling of energy expenditure and energy intake, it is possible that the physical activity levels in the general population are also able to influence appetite responses. In our previous studies we have noted that subjects who regularly participate in recreational exercise appeared better able to compensate for differences in pre-load energy content than those who did not (Long, 2000). In addition, recent data showing good compensation for differences in energy intake following periods of exercise in male subjects who undertake regular exercise (non-athletes) (King *et al.* 1999) suggest that exercise may improve the sensitivity of the appetite control system to manipulations of energy intake. If exercise does improve the sensitivity of an individual in detecting differences in energy intake, regular physical activity would therefore be important for the regulation of body weight not only through increases in energy expenditure but also improved appetite regulation.

The present study therefore tested the hypothesis that habitual exercisers demonstrate an increased accuracy of regulation of food intake in compensation for previous dietary energy intake. Short-term appetite responses following high- and low-energy preloads were measured in individuals who undertook regular exercise compared with those who undertook no exercise. Compensation for preload energy manipulations in subsequent food intake was also investigated to determine whether habitual exercise levels affected the subjects' ability to detect differences in preload energy manipulations and adjust energy intake accordingly.

## Materials and methods

### Subjects

Twenty-three healthy male subjects (age range 18–40 years) of normal weight for height (mean BMI 23.7 (SD 2.8) kg/m<sup>2</sup>) were recruited on the basis of their habitual exercise levels. All volunteers were asked to complete the Dutch Eating Behaviour Questionnaire (Van Strien *et al.* 1986) during recruitment, and only those subjects with scores of <3.5 in any one section were recruited

for participation in the study. Subjects were initially asked to rate their participation in exercise as one of three categories: one session or less per week (habitual non-exercisers), two to three sessions per week (habitual moderate exercisers) or four or more sessions per week (habitual high exercisers). One exercise session was defined as at least 40 min of moderate to high intensity activity. In addition, in-house activity diaries were completed on two separate occasions for 7 d, in order to verify subjects' self-related exercise levels, and follow-up interviews given after completion of the study to check habitual exercise levels during the previous 3 months. Subjects were then assigned to the representative group. In only one subject was there any discrepancy between these methods of assessing exercise; in this subject self-reported exercise levels were taken, due to exceptional personal circumstances at the time of recording his activity diary.

Characteristics of each group are described in Table 1. Subjects showed no significant differences between groups in their Dutch Eating Behaviour Questionnaire scores or BMI. Before commencement of the study all volunteers were instructed that they must refrain from alcohol and exercise for the 24 h before each test occasion.

### Preloads and measurement of appetite

Two preload meals were developed to provide high and low-energy through the manipulation of carbohydrate content. Each preload was given as a 450 ml milk-shake consisting of double cream, maltodextrin and sucrose, and made up to volume with water. Vanilla essence (1.5 ml) was added to each preload to improve palatability. The low-energy preload (LE) provided 1008 kJ and the high-energy preload (HE) provided 2513 kJ (Table 2).

Food intake after consumption of the preload was assessed using an *ad libitum* buffet test meal (Rogers, 1993) which enabled subjects to choose from a range of familiar foods, appropriate to the time of day. Subjects were asked to rank various buffet food items in order of preference. They were then offered their second and third choices of sandwich fillings and food types. The total energy available from the buffet ranged from 10751 kJ to 12611 kJ depending on subjects' preferences and the subsequent food items offered; the protein:fat:carbohydrate ratio was approximately 13:38:49 % energy. The number and range of food items presented to each subject was identical on each test occasion. The buffet food was weighed

before and re-weighed after each subject had finished eating, to allow calculation of energy and macronutrient intake. All dietary analyses were performed using Diet 5 for Windows (The Robert Gordon University, Aberdeen).

Subjective assessment of hunger and satiety was made using self-rating visual analogue scales (VAS) (Rogers, 1993). Each scale consisted of a 10 cm line anchored at either end with extreme statements; for example, the scale 'how hungry do you feel?' ranges from 'not at all hungry' to 'as hungry as I have ever felt'. Subjects were instructed to rate themselves by marking the scale at the point which was most appropriate to their feeling at that time. Ratings on the scales were converted to a score in centimetres for statistical analysis of the appetite responses to each treatment.

#### Study protocol

Using a randomised single-blind crossover design the appetite and food intake response to each preload was investigated. Subjects were instructed to consume their evening meal before midnight on the night before each study occasion, and to consume the same meal before the next study occasion.

On the morning of each study subjects were asked to consume their normal breakfast before 09.30 hours, and to consume the same breakfast on each test occasion. These were recorded in a diet diary. Following breakfast

**Fig. 1.** Buffet test meal energy intake following either a low- (■) or a high-energy (▒) preload in a group of habitual non-exercisers ( $n$  9) or exercisers ( $n$  14). Values are means and standard errors of the mean. Columns sharing the same symbol denote significant differences between groups: \* $P$ <0.01, † $P$ <0.05).

subjects were instructed to eat or drink nothing except water until arrival at the investigation unit at 11.15 hours. After arrival at the investigation unit subjects had a 15 min rest period, and were then asked to complete baseline VAS ratings. Subjects were then offered either the LE or HE preload and instructed to drink at a steady pace. A second VAS rating was completed after consumption of the preload. Further VAS ratings were then completed at 20 min intervals for the next 60 min, after which time subjects were offered the *ad libitum* buffet test meal. Subjects were instructed to eat until comfortably full from this meal, and to prevent over-consumption due to freely available food, subjects were informed they may take away any food they did not want to eat at that time. Energy and macronutrient intakes were calculated from the test meal. Following the buffet test meal consumption subjects completed a final set of VAS ratings and were then free to resume their normal activities.

#### Statistical analyses

Differences in buffet test meal intake after the high and low-energy preloads were compared within each exercise group using a paired  $t$  test (2-tailed). Differences in intake between exercise groups following individual preloads were compared using one-way ANOVA and any differences were localised using the Tukey *post-hoc* test. Data were tested for normality of distribution and equality of variance with the Komologov–Smirnov test and Bartlett's test for equal variance respectively.

Differences between buffet test meal energy intakes between the high- and low-energy preloads were used to calculate the compensation within subject groups for the difference in preload energy ((difference in buffet test meal energy intake/difference in preload energy)  $\times$  100).

Hunger and satiety ratings between the high- and low-energy preload within each exercise group were analysed using repeated measures ANCOVA. The baseline rating (–5 min) was used as the covariate, with preload and time (10 to 60 min) as the repeated measures factors. Ratings following the buffet test meal were analysed separately using a paired, 2-tailed  $t$  test as they were no longer primarily responsive to preload manipulations. To assess differences in hunger and satiety between exercise groups the difference in ratings between the high- and low-energy preloads was calculated for each group. These differences were then analysed using ANCOVA, using the –5 min value as the covariate. Exercise group was an independent variable with time (10 to 60 min) as the repeated measures factor.

Results are expressed as mean and SEM unless otherwise stated.  $P$  values of <0.05 were considered to be statistically significant. Statistical analyses were carried out using the software package Statistica for Windows (Statsoft, Tulsa, OK, USA).

## Results

#### Ad libitum buffet test meal intake

The two exercise groups (habitual moderate and high

exercise) were initially combined and compared with the habitual non-exercise group. Buffet intake for these groups is shown in Fig. 1. Buffet test meal energy intakes in the non-exercising group were not significantly different following the LE or HE preloads, but the exercise group significantly reduced their energy intake following the HE, compared with the LE, preload ( $P=0.0035$ ). Buffet energy intake was not significantly different between exercisers and non-exercisers following the LE preload, but following the HE preload the non-exercise group had significantly higher buffet energy intakes than the exercise group ( $P=0.0274$ ). When the exercise group was subdivided into moderate and high exercisers, a broadly similar pattern of response was seen for the two groups. Moderate exercisers showed a reduced buffet energy intake following the HE compared with the LE preload ( $P=0.046$ ). This difference just failed to achieve statistical significance for the high-exercise group ( $P=0.057$ ).

Buffet macronutrient intake in exercisers and non-exercisers following the high- and low-energy preloads is shown in Fig. 2. The ratios of macronutrients selected in the buffet were similar to those offered, and did not differ between the exercisers and non-exercisers. The non-exercise group demonstrated no changes in macronutrient intake following the two preload conditions, whereas the exercise group demonstrated significantly reduced intakes for all three macronutrients, carbohydrate ( $P=0.47$ ), fat ( $P=0.00063$ ) and protein ( $P=0.0128$ ), following the HE compared with the LE preload. A similar pattern was observed for both exercise groups. Differences in macronutrient intake reached significance with respect to fat in the moderate-exercise group ( $P=0.0234$ ), and carbohydrate in the high exercise group ( $P=0.0476$ ).

Habitual non-exercisers were found to have a low level of energy compensation in the buffet test meal for differences in preload energy intake, at 7%. However, habitual exercisers had a good level of compensation, at 90%. Mean compensation levels for the moderate- and high-exercise groups were 99% and 82% respectively.

**Fig. 2.** Buffet test meal macronutrient intake following either a low-energy (■, □) or a high-energy (▨, □) preload in a group of habitual non-exercisers (■, ▨;  $n=9$ ) or exercisers (□, □;  $n=14$ ). Values are means and standard errors of the mean. Column sharing the same symbol denote significant differences between groups: \* $P<0.05$ , † $P<0.025$ , ‡ $P<0.01$ .

### Subjective assessment of hunger and satiety

Self-assessed hunger and satiety ratings in exercisers and non-exercisers before and after the low- and high-energy preloads, and after the *ad libitum* buffet test meal, are shown in Tables 3 and 4. The non-exercise group scored significantly higher on their self-ratings of hunger at the start of the study, before preload consumption, compared with the exercise group ( $P<0.01$ ), with both the LE and HE preload. However there were no significant differences between hunger or satiety ratings following the high- or low-energy preloads for either the habitual exercisers or non-exercisers. Hunger and satiety ratings following the buffet test meal were also similar between groups regardless of preload.

### Pre-study breakfast intake

Breakfast energy intake was similar on each experimental occasion for both the exercise and non-exercise groups. There was no significant difference in breakfast energy intake (mean of the two occasions) between the habitual exercisers and non-exercisers (breakfast energy intake of habitual non-exercisers *v.* exercisers, 7570 (SD 2546) kJ *v.* 7354 (SD 2570) kJ,  $P=0.8$ ).

## Discussion

Exercise has recently been shown to result in a good compensatory response to covert preload manipulation (King *et al.* 1999), suggesting that exercise may improve the sensitivity of the appetite control system in its response to previous dietary intake. We have previously undertaken studies in our laboratory using similar preloads and experimental design as the present study, in a group of subjects where exercise levels were not taken into account. Whilst the group as a whole showed a significant ability to distinguish between high- and low-energy preloads (Long, 2000), we observed that a few extremely sedentary individuals in the group were unable to compensate for preload energy. Data from the current investigation support a role for exercise in improving the ability of human subjects to compensate for differences in preload energy. Following consumption of high- or low-energy preloads, the habitual non-exercise group showed little compensatory response for the difference in preload energy in their subsequent food intake. *Ad libitum* buffet test meal intake was not significantly altered by manipulating preload energy content, with this group showing only a 7% compensation for differences in preload energy. In contrast, *ad libitum* buffet test meal intake in habitual exercisers was significantly smaller following the high-energy compared with the low-energy preload, and the exercise group as a whole achieved a 90% compensation for previous energy intake. When the exercise group was divided into moderate and high exercisers, this sensitivity to previous energy intake was apparent in both groups. It thus appears that relatively modest exercise (two to three sessions/week of moderate- or high-intensity activity) is sufficient to ensure accurate short-term compensation for previous energy intake.

**Table 3.** Self-assessed hunger ratings at intervals before and after low-(LE) and high-energy (HE) preloads, and after *ad libitum* buffet test meal intake, in habitual non-exercisers (*n* 9) and exercisers (*n* 14)  
(Mean values and standard errors of the mean)

	- 10 min		10 min		20 min		40 min		55 min		Post buffet	
	Mean	SEM	Mean	SEM	Mean	SEM	Mean	SEM	Mean	SEM	Mean	SEM
Non-exercisers												
LE preload	6.15	0.69	4.91	0.89	4.89	0.79	5.68	0.91	6.56	0.75	1.68	0.60
HE preload	6.73	0.52	5.59	0.70	5.19	0.81	5.42	0.86	6.50	0.76	1.67	0.53
Exercisers												
LE preload	4.66	0.68	4.26	0.68	4.63	0.62	5.40	0.55	6.34	0.50	1.31	0.36
HE preload	4.88	0.69	4.29	0.65	4.79	0.72	4.74	0.73	5.40	0.68	1.16	0.23

Although the difference in compensation between moderate- and high-exercise groups was small, mean energy compensation was higher in the moderate than the high exercisers. This dissociation suggests that while food intake regulation may be improved at some levels of habitual exercise, dissociation in appetite responses could occur at higher exercise levels. This dissociation would support the observation of a discordance in energy intake and energy expenditure in very inactive and very active rats, with moderately active animals exhibiting a tight control between the two (Mayer *et al.* 1954).

Self-rated assessment of hunger and satiety followed the expected reciprocal relationship. There were, however, no significant differences in either hunger or satiety ratings between the low- and high-energy preloads in either the exercise or non-exercise group, suggesting that although food regulation was improved in subjects with higher habitual exercise levels, this was not directly related to differences in subjective feelings of hunger or satiety. It thus appears that differences in appetite control between the habitual exercisers and exercisers in the present study manifest themselves primarily as differences in intake. It is therefore possible that exercise increases sensitivity to satiety signals rather than hunger signals, and that food intake is more readily controlled through the cessation of an eating episode. Such a mechanism of appetite regulation would agree with previous work suggesting that obese subjects are less sensitive than lean subjects to short-term, post-ingestive satiety signals (Spiegel *et al.* 1989), and could help explain regular overconsumption in obese

persons. Habitual exercisers scored significantly lower in their self-ratings of hunger at the start of the study, before preload consumption. The reason for this finding is unclear. Acute exercise, even at high intensity and/or duration has been found to have little sustained effect on subsequent hunger ratings (Imbeault *et al.* 1997; King *et al.* 1997a,b). In view of the rapid drop-off rate for any exercise-induced anorexia that is seen (King *et al.* 1994), the ability of habitual exercise to influence hunger by 'stockpiling' these short-lived anorectic responses seems unlikely. Subjects were asked to consume their usual breakfast, giving rise to the possibility that differences in habitual breakfast energy intake could account for the initial differences in self-assessed hunger observed between the groups; however, pre-study breakfast energy intake was similar between the groups. This does not preclude the possibility of the initial differences occurring because of the choice of breakfast food; a wide range of different breakfast foods were habitually consumed by the subjects.

The mechanisms whereby habitual exercise might affect appetite remains to be established. However, one suggested mechanism whereby exercise may increase the accuracy of appetite regulation could be via effects of exercise on insulin sensitivity. Evidence to support an increase in insulin sensitivity in response to exercise is well-reported (Aldred *et al.* 1995; Poehlman *et al.* 2000), as is the evidence to implicate insulin sensitivity in the regulation of appetite (Haber *et al.* 1977; Holt *et al.* 1992). Measures of hunger and satiety have also previously been shown to

**Table 4.** Self-assessed satiety ratings at intervals before and after low-(LE) and high-energy (HE) preloads, and after *ad libitum* buffet test meal intake, in habitual non-exercisers (*n* 9) and exercisers (*n* 14)

be closely related to changes in circulating glucose concentrations (Melanson *et al.* 1999), rates of glucose absorption (Kishnamacher & Mickelsen, 1987), and hence insulin activity (Leathwood & Pollet, 1988). Another potential mechanism could be modulation of gastrointestinal hormones which influence appetite. The gastrointestinal hormones cholecystokinin and glucagon-like peptide-1 are both implicated in the short-term physiological control of appetite (Lieverse *et al.* 1995; Flint *et al.* 1998). Plasma cholecystokinin levels are raised following acute exercise in man (Bailey *et al.* 2001), whereas the effect of exercise on glucagon-like peptide-1 is unknown.

Our experimental protocol did not allow us to detect whether there was a difference in energy turnover between the exercisers and non-exercisers. The mean additional daily energy expenditure in the exercise group due to their exercise sessions was estimated from subjects' activity diaries at approximately 1500 kJ/d, some 15% of a typical 24 h energy expenditure of 10000 kJ (Frayn, 1996). It is therefore not unreasonable to suppose that daily energy expenditure might be higher in the exercise group.

Whilst the present study suggests an association between physical activity level and appetite regulation, it does not, however, show that exercise is a causal factor in enabling increasingly accurate compensation for previous energy intake. The role of lifestyle and cognitive differences between people who undertake regular exercise and those who do not must be considered, as this represents a large potential difference for feeding behaviour. Whilst the use of the Dutch Eating Behaviour Questionnaire in the current investigation enabled the subject groups to be balanced in terms of their dietary restraint, emotionality and externality, and covert preload manipulations were aimed to minimise the influence of external processes in the present investigation, the role of other beliefs and cognitive differences was not assessed. Future use of an intervention design whereby habitual non-exercisers are prescribed an exercise regimen, would enable the effect of exercise itself to be investigated.

The prevalence of obesity, with its attendant health risks, is steadily increasing in the UK (Fehily, 1999). Recent studies have classified some 29% of the population as sedentary; only 5% of women participate in regular vigorous physical activity (Fentem & Walker, 1995). The present study demonstrates that habitual exercisers have an increased short-term accuracy of regulation of food intake in compensation for previous (preload) energy intake, and provides additional support for advocating regular exercise in the prevention of overweight and obesity.
