Submitted 1 October 2009: Accepted 1 June 2010: First published online 16 July 2010

Abstract

Objective: To gain insight into intervention components targeted specifically to mothers of young children that may contribute to attendance and effectiveness on physical activity and healthy eating.

Design: Systematic literature searches were performed using MEDLINE, Embase and cited references. Articles were included if they evaluated the effectiveness of a lifestyle intervention to promote physical activity and/or healthy eating in an experimental design among mothers with young children (age 0–5 years). Data were extracted on study characteristics, intervention components targeted towards mothers with young children, attendance and effectiveness. Extracted data were analysed in a descriptive manner.

Results: Eleven articles describing twelve interventions met the inclusion criteria. Of the six studies that measured attendance, two reported high attendance. Embedding the intervention within routine visits to child health clinics seems to increase attendance. Three studies found significant effects on physical activity and three on healthy eating. Effective interventions directed at physical activity included components such as counselling on mother-specific barriers or community involvement in intervention development and implementation. One of the three interventions that effectively increased healthy eating had components targeted at mothers (i.e. used targeted motivational appeals).

Conclusions: The number of experimental intervention studies for promoting physical activity and healthy eating among new mothers is limited. However, useful first recommendations can be set for targeting interventions towards mothers, in particular for promoting attendance and physical activity. More insight is required about the need for targeting health promotion programmes at new mothers, especially of those directed at nutritional behaviour.

Follow-up studies among adults show that weight gain in young women is, on average, relatively large compared with older women1-5. Excessive weight gain during pregnancy, failure to lose weight in an appreciable period of time postpartum and weight gain during the postpartum period may well partly explain this weight gain among young women4-6. New mothers are more likely to gain weight than young adult women without children7. In addition, longitudinal studies have shown that postpartum weight retention predicts overweight in the long term4,5. Therefore, promoting weight control among new mothers is valuable in obesity prevention.

A decrease in physical activity during the transition into motherhood may explain the higher increase in weight gain among new mothers compared with non-mothers. A meta-analysis showed that mothers were less likely to be physically active than fathers and non-parents8. In particular, mothers of young children (under the age of 5 years) seem to be at risk for physical inactivity9,10. Changes in nutritional behaviour before and after pregnancy are found inconsistently11-13. However, this does not mean that there is no room left to improve nutritional behaviour among mothers. An unhealthy diet and a decrease in physical activity are both related to weight gain among mothers with young children7,14,15.

Preliminary findings of a recently published Cochrane review16 extracted from six studies showed that among women recruited in the postpartum period (up to 12 months...
postpartum) a prescribed diet combined with structured exercise, or diet alone, compared with usual care, seemed to enhance weight loss\textsuperscript{(16)}. However, this Cochrane review focused on the effect of a change in diet or exercise on change in weight without examining the factors that lead to behaviour change. In order to develop weight-loss programmes, it is useful to have insight into how these behaviours can be promoted.

In addition, it seems worthwhile to look at how mothers can be encouraged to attend such programmes. The years it takes to establish a young family involve a major life transition for women in terms of their social, occupational and biological lives\textsuperscript{(17)}. Most mothers of young children experience some constraints, for example lack of time and energy, and the responsibilities of child care. These factors may influence their interest in and ability to attend interventions\textsuperscript{(18)}.

Targeting nutrition and physical activity interventions to these mother-specific factors may enhance both their effectiveness and attendance rate. Therefore, the purpose of the present review is to gain insight into targeted intervention components which may contribute to the attendance and effectiveness of interventions promoting physical activity and/or healthy eating to mothers with young children (0–5 years).

Materials and methods

Search strategy and data sources

Intervention studies were identified through a structured electronic database search in OVID Embase and MEDLINE. The search strategy, shown in Table 1, included searching on words in the title or abstract and MeSH terms. The search was limited to articles with MeSH term ‘human’ (or ‘humans’ in MEDLINE) and articles published from 1997 to 2009.

Selection criteria

Studies eligible for inclusion were: intervention studies aimed at promotion of physical activity and/or healthy eating; the target group was mothers (aged 18+ years) with young children (aged 0–5 years); the study design included a pre- and post-measurement among an intervention and a control group. Studies were excluded if the intervention was a prescribed diet or exercise programme with no attention paid to lifestyle change (e.g. sessions with prescribed exercise to achieve a certain percentage of the heart rate reserve for a certain amount of time). Also, studies were excluded if the study population consisted of mothers with mental health problems because this was considered to be a different subpopulation. Finally, studies were excluded if no information was available about the age of the children. An exception was made for participants of the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), since this programme provides food, nutrition counselling and access to health resources specifically for low-income pregnant and postpartum women with children up to the age of 5 years in the USA (http://www.fns.usda.gov/wic/).

\textsuperscript{*}WIC, Special Supplemental Nutrition Program for Women, Infants, and Children. The WIC programme provides food, nutrition counselling and access to health resources for low-income pregnant and postpartum women with children up to the age of 5 years in the USA (http://www.fns.usda.gov/wic/).

Procedure

The titles and abstracts were assessed by the first author (M.A.H.). In cases of doubt the second author was consulted (K.H.). If a reference was considered to be relevant, the full paper was retrieved. Full papers were assessed against the review selection criteria. Reference lists of relevant articles were scanned. Extracted data included study characteristics, intervention characteristics, intervention components targeted at mothers, and reported intervention attendance and effectiveness. By intervention components targeted at mothers, we mean the intervention components adapted to the situation of mothers with young children. By attendance, we mean not only attendance at intervention classes but also exposure to the intervention in other ways (i.e. dose received).

Information on the characteristics of the studies was collected so that the quality and generalizability of the studies could be assessed. The following information about study characteristics was extracted: the country where the study was conducted, design (true experiment or quasi-experiment), description of the intervention and comparison group, response and attrition rate, and primary outcome measures.

Additionally, data were extracted separately for intervention components presumed to be related to attendance and effectiveness. Information on both kinds of results is important, since a low attendance or a low effectiveness will result in a low impact of the intervention. The results were analysed in a descriptive manner.

For attendance, intervention components targeted at mothers were summarized. Subsequently, the intervention components in studies with a low attendance were compared with those in studies with a high attendance. In addition, information was collected about possible explanations for non-attendance.
For effectiveness on physical activity and healthy eating, intervention components specifically targeted at mothers were summarized, related to effectiveness (statistically significant effects or not) and additional information was collected on the possible explanations for their effectiveness. Furthermore, if key elements of a systematic development of interventions were used (use of formative research, theory, behavioural change strategies, evidence and targeting other characteristics than being a mother), these elements were then also summarized. Such elements should be taken into account when interpreting the results of the relationship between targeted components and the effectiveness of interventions because a systematic intervention development increases the likelihood of obtaining the intended positive effects.

Results

Study selection
The initial search identified 1556 publications. After eliminating duplicates and reviewing the titles and abstracts of these publications, the total was reduced to forty-two. These forty-two articles were completely reviewed, after which thirty-one publications were excluded because they did not meet one or more of the inclusion criteria. The main reasons for exclusion were lack of a control group; a different outcome measurement than physical activity or nutritional behaviour; or because mothers of children above 5 years of age were included in the study. Moreover, four review articles were found, all describing studies which mainly investigated the relationship between weight-related behaviours and weight only using prescribed diet or exercise with no attention for lifestyle change. Equally, two intervention studies were excluded for this reason. Finally, some articles seemed to report the results of the same study because they described the same intervention and the same number of participants. In one case, the article was chosen which described the effect evaluation instead of the feasibility study. In the other two articles, cases were selected which evaluated the effect on actual health-related behaviour instead of on the stages of change or purchasing of fresh fruit and vegetables. After checking references no other relevant articles were found. Therefore, a total of eleven articles were eligible, describing twelve interventions (Table 2).

Study characteristics
The eligible studies differed on many characteristics (Table 3). Most of the studies were conducted in the USA, two in Australia, one in Canada and one in Finland. Four interventions were implemented in a clinical setting, three in a community setting and five interventions were implemented within or alongside the WIC. Three studies were quasi-experiments and eight true experiments.

Six studies included only postpartum mothers with children up to the age of 1 year, in contrast with the five other studies which included mothers of children up to 5 years. Moreover, the study populations differed on socio-economic and ethnic composition. The American studies directed at WIC mothers mainly included a relatively high percentage of low-income women and women from minority groups. Control groups consisted mainly of usual care or no intervention. The study population size varied from forty-four to 3122 participants.

The variation in response rates was large, 30.8% to 91.2%, but almost half of the studies gave no information about response rates. No information could be obtained about response rate for one study since respondents were recruited passively through a local community newspaper article on postnatal fitness. In the other studies, respondents were recruited actively, i.e. were personally approached to participate in the study. Short-term attrition rates varied from 7.6% to 31.0%.

Three interventions were directed at promoting healthy eating, physical activity as well as weight change; four interventions were aimed at promoting healthy eating; and four at physical activity. In all studies, nutritional behaviour was measured by self-reports; physical activity by self-reports or objective measurement (pedometer/accelerometer); and weight loss by self-reports or anthropometric measurements.

Attendance
Within the six studies that reported attendance, full attendance ranged from 9% to 92% (Table 4). In two studies, subgroup analyses were performed. Older (>50 years) and higher educated mothers were more likely to attend in both studies. In one study participants were more likely to be white, while in the other study there was no difference regarding attendance between ethnic groups. Moreover, married, higher-income and unemployed mothers were more likely to attend compared with mothers who did not participate.

Components within intervention studies reaching a low v. a high attendance
Two studies succeeded in reaching a high attendance of mothers (Table 4). The intervention of Kinnumen et al. was embedded within routine visits to child health clinics, normally attended by 98% of the target population. This resulted in a 92% attendance to their intervention. Furthermore, Cramp and Brawley reached an attendance of 75%. Their attempts involved conducting the intervention in a community-based fitness facility and providing child care for a nominal fee. Other interventions whereby child care was provided or an activity with mothers and children was organized did not result in high attendance.

Moreover, several other approaches were used in order to increase attendance among mothers with young
Table 2 Overview of interventions directed at mothers with young children to promote healthy eating and/or physical activity

**Nutrition interventions**

Campbell et al. (2004)\(^{(28)}\): The intervention, Foodsmart, concerned interactive tailored nutrition education that took approximately 20–25 min to complete on the computer. The intervention included four main components: (i) a full-motion video soap opera; (ii) interactive 'inforcials'; (iii) tailored dietary feedback; and (iv) psychosocial feedback determined by baseline measurement.

Havas et al. (1998)\(^{(29)}\): The intervention, the Maryland WIC 5-A-Day Promotion Program, consisted of three components over a 6-month period: (i) three nutrition sessions conducted by peer educators; (ii) printed materials and visual reminders (a photo novella which served as a guidebook for group discussions and five cue cards; a booklet of recipes; a children’s activity book focused on F&V; and a videotape showing children singing about F&V; a refrigerator magnet with the programme’s logo; and a calendar/reminder sheets containing information about future nutrition sessions); and (iii) direct mail (four different tailored letters accompanied by a tip sheet and a clue card).

Havas et al. (2003)\(^{(30)}\): The multidimensional intervention Maryland WIC Food For Life (FFL) Program was targeted at participants’ stages of change and included: (i) a 5 min video featuring enthusiastic participants from the pilot study; (ii) an attractive FFL brochure; (iii) individualized feedback on their baseline FFQ; (iv) a kick-off fair; (v) four 45 min workshops; (vi) newsletters; (vii) mail packets; (viii) personalized invitations; (ix) behaviour-reinforcing incentives; and (x) phone calls over a 6-month period.

Herman et al. (2008)\(^{(31)}\): Participants in the two intervention sites were issued US$10 worth of vouchers per week, in US$1 units for the supermarket site and in US$2 units for the farmers’ market site, to buy produce of the participants’ choice. Vouchers were issued bimonthly and could be spent over the ensuing 2-month period.

**Nutrition and PA interventions**

Kinnunen et al. (2007)\(^{(32)}\): The intervention included individual counselling on PA (one primary counselling session and four booster sessions) and diet (one primary counselling session and three booster sessions in addition to the PA booster sessions) during five routine visits to a public health nurse and an option to attend exercise classes held once per week for 45–60 min.

Leermakers et al. (1998)\(^{(33)}\): A 6-month behavioural weight-loss intervention delivered via correspondence, which focused on low-fat/low-calorie eating habits and increasing PA. This intervention included three components: (i) two group sessions; (ii) correspondence materials (six written lessons about nutrition, exercise and behaviour change strategies); and (iii) telephone contact (weekly or biweekly).

Østbye et al. (2009)\(^{(34)}\): Active Mothers Postpartum consisted of eight healthy eating sessions (Mom’s Time Out (MTO) classes), ten PA group sessions (ACTIVMOMS classes) and six telephone-counselling sessions over a 9-month period. Participants were also provided a study notebook, pedometer and sport stroller.

**PA interventions**

Cramp and Brawley (2006)\(^{(35)}\): Participants in the intervention condition received standard exercise training classes (SE) plus a group-mediated cognitive behavioural intervention (GMCB). SE consisted of an intensive phase (4 weeks) of exercise classes twice weekly immediately followed by 4 weeks of a home-based phase in which participants were encouraged to implement their own exercise regime. In addition, during the intensive phase, participants received six 20 min GMCB sessions consisting of self-regulatory skill training. During the home-based phase, one telephone contact was provided.

Fahrenwald et al. (2004)\(^{(36)}\): Moms on the Move consisted of three components: (i) provider counselling supplemented with (ii) an interactive trifolded, two-sided coloured brochure and (iii) four structured, biweekly provider-delivered telephone contacts to promote PA.

Miller et al. (2002)\(^{(37)}\): Group 2 received a print intervention. Group 3 received both the print intervention and an invitation to attend a meeting at their child care centre to discuss the development of local strategies for the promotion of PA among mothers of young children. This formed the basis for the development of intervention strategies (implemented through collaboration among participants, researchers and community organizations). In addition, group 3 received a PA directory with avenues for accessing information about PA opportunities in their local community; a telephone call was made after the discussion group meetings; and notice boards were displayed to encourage dissemination of information about local opportunities for PA.

Watson et al. (2005)\(^{(38)}\): Nurses invited mothers in the intervention area to join pram walking groups. The pram walking groups were held once a week in a number of locations across the intervention area and were approximately 1 h in duration.

WIC, Special Supplemental Nutrition Program for Women, Infants, and Children; F&V, fruit and vegetables; PA, physical activity.

<tbody>
<tr>
<td><strong>Havas et al. (1998)</strong></td>
<td>Short-term effect</td>
<td>1. Formative research&lt;br&gt;• Focus group discussions and central intercept interviews&lt;br&gt;• Pilot study&lt;br&gt;2. Theoretical framework&lt;br&gt;• SoC&lt;br&gt;3. Behaviour change strategies&lt;br&gt;• EDU, PC, SS, PE, GP, GS, RF, DS&lt;br&gt;4. Evidence-based&lt;br&gt;• Peer educators&lt;br&gt;5. Targeted to SES/ethnicity&lt;br&gt;• Peer educators</td>
<td>Motivational appeals directed to mothers&lt;br&gt;• Two major motivational appeals were used to stimulate adoption of the targeted behaviours: (i) set a good example for your children by eating more F&amp;V; and (ii) take care of yourself by eating more F&amp;V not only during pregnancy but also afterwards&lt;br&gt;A photo novella with a mother role model as guidebook for nutrition sessions&lt;br&gt;Ms. New-mother (a WIC participant) who modelled the activities leading to increased F&amp;V consumption, served as each participant’s guidebook for writing thoughts about F&amp;V intake, setting goals, choosing behavioural strategies to achieve goals, and identifying and overcoming barriers&lt;br&gt;Peer educators&lt;br&gt;During nutrition sessions, peer educators guided participants through exercises in the photo novella, facilitated discussion and provided social support to help them achieve their goals</td>
<td>Mediation&lt;br&gt;• Changes in self-efficacy, attitudes, social support and knowledge of national consumption recommendations accounted for most of the intervention effect on increased consumption&lt;br&gt;Attendance effectiveness relationship&lt;br&gt;• A strong relationship between attendance at nutrition sessions and changes in consumption was found; the more sessions attended, the more F&amp;V servings consumed</td>
</tr>
</tbody>
</table>

**Significant effect on healthy eating**

Mean increases in daily consumption of F&V were larger among intervention participants (0.56 (so 0.11) servings) v. control participants (0.13 (so 0.17) servings; $P = 0.002$)

**Effect on subgroups**

- White women, women <30 years of age, high-school graduates, married or not working women showed significantly greater increases in consumption
- Significant increases in consumption of F&V were found for intervention participants in pre-contemplation, contemplation and preparation stage at baseline, but not among those in action and maintenance stages

Long-term effect

- Effects on F&V remained significant at 1 year

**Havas et al. (2003)**

Difference in change in intervention participants v. controls was $-1.62$ (so 0.33) %E from fat ($P < 0.001$), 0.4 (so 0.11) servings of F&V ($P < 0.001$) and 1.01 (so 0.31) g fibre ($P = 0.001$)

**Effect on subgroups**

- Significant differences between intervention and controls in both black and white participants
- Larger change among women aged <30 years and with at least high-school education

Long-term effect

- Effects remained after 1 year for fat ($-0.74$ (so 0.38) %E v. 0.67 (so 0.41) %E, $P = 0.03$) and for F&V consumption ($-0.1$ (so 0.13) v. $-0.32$ (so 0.14) servings, $P = 0.03$), but not for fibre

1. Formative research<br>• Focus groups discussions and central intercept interviews<br>• Pilot study<br>2. Theoretical framework<br>• TTM, SLT<br>3. Behaviour change strategies<br>• EDU, SS, PE, GS, ST<br>4. Targeted to SES/ethnicity<br>• Peer educators<br>5. Evidence-based<br>• Peer educators for assuring a culturally sensitive intervention to low-income participants<br>Newsletters had large fonts and simple illustrations<br>In phase 2: simplified messages and a free bag of food

**Attendance effectiveness relationship**

- The more sessions attended, the greater the changes in intake. This applied to all three dietary variables

<th>Intervention components targeted towards mothers aimed to promote lifestyle change</th>
<th>Explanations for effectiveness</th>
</tr>
</thead>
</table>
| Østbye et al. (2009) (33) | Short-term effect on food intake  
- Mean energy intake and %E from fat decreased in both groups, effects in groups were not significantly different  
- No differences on soda, sweetened drinks, fries or chips, or F&V per day, or fast food per week | 1. Formative research  
- Survey about interest and preferences for weight loss intervention\(^{(31)}\)  
- Pilot test of the intervention materials  
2. Behaviour change strategies  
- EDU, GP, DS, ST | Exercise classes developed specifically for postpartum women  
- ACTIVMOMS sessions included specific exercises designed to enhance recovery from pregnancy-related changes in body structure and function. Using a stroller or front-facing baby carrier, classes enabled mothers to exercise with their babies. The classes were taught by certified postpartum exercise instructors  
Discussion of barriers to PA and weight loss in general common for the postpartum period  
- Barriers for exercise and PA shared by all new mothers were emphasized and discussed as a group\(^{(52)}\)  
- Educational activities helped women develop strategies to overcome common barriers to weight loss in the postpartum period, such as lack of time, energy and motivation\(^{(52)}\) | Attendance effectiveness relationship  
- Class participation significantly associated with weight change in bivariate analysis \(P = 0.01\), but not with change in diet or PA  
- Multivariable analysis controlling for age, race, education, income and baseline BMI attenuated effect of class participation on weight change \(P = 0.57\)  
- Completion of counselling calls not associated with weight or behaviour outcomes |
| | Short-term effect on PA  
- Both groups increased bouts of activity per week and total minutes of activity per week, effects in groups were not significantly different  
- No differences on sedentary behaviour (TV hours per day)  
- Women in both groups experienced modest weight loss, effects in groups were not significantly different  
- No differences on return to pre-pregnancy weight, % weight loss, change in BMI category, and proportion losing ≥4.5 or 1.0 kg | | |
| Cramp and Brawley (2006) (36) | Short-term effect  
- Mean volume of moderate to vigorous PA \(\text{frequency} \times \text{duration}\) in intervention group increased more (from 126-34 (so 152-26) to 400-38 (so 288-64)) than in control group (from 125-32 (so 131-25) to 222-24 (so 177-37); \(F(1,52) = 8.36, P < 0.01\) | 1. Theoretical framework  
- SCT, SET  
2. Behaviour change strategies  
- GS, SM, ST, FB  
3. Evidence-based  
- Theory-based intervention framed in both SCT and group dynamics  
4. Targeted to SES/ethnicity  
- Free-of-charge use of a large commercial gym | Group counselling focused on how to overcome postnatal-specific barriers to PA  
- Focus on developing self-regulatory skills for self-management of PA and to overcome postnatal-specific barriers to self-managed PA (e.g. goal setting, defining barriers, brainstorm of barriers and strategies to overcome barriers)  
- Creation of a ‘back-up’ PA plan in the event that mothers were unable to engage in planned PA | |
| | Significant effect on PA | | | |

1. Formative research  
- Survey about interest and preferences for weight loss intervention\(^{(31)}\)  
- Pilot test of the intervention materials  
2. Behaviour change strategies  
- EDU, GP, DS, ST | Exercise classes developed specifically for postpartum women  
- ACTIVMOMS sessions included specific exercises designed to enhance recovery from pregnancy-related changes in body structure and function. </table>
| Fahrenwald et al. (2004) 32 | Short-term effect | 1. Formative research  
2. Theoretical framework  
3. Behaviour change strategies  
4. Evidence-based  
5. Targeted to SES/ethnicity  
   - 7th grade reading level of the brochure | A brochure with pros, cons and strategies to overcome barriers to PA identified by mother  
   - A brochure with examples of key pros and cons to PA identified by WIC mothers, and strategies to overcome frequently cited barriers to PA (e.g. serving as a positive role model for children was emphasized; mothers were asked to think about how their PA can benefit the whole family)  
   - Provider counselling  
   - The brochure was the guidebook during provider counselling sessions. Mothers had to identify two desired benefits of PA, two personal barriers, and planned ways to overcome these barriers | No mediation  
   - Changes in PA outcome variables were not mediated through changes in stages of PA behaviour change, exercise benefits/barriers, self-efficacy for exercise, processes of exercise adoption, i.e. self-liberation, counter-conditioning, environmental re-evaluation, and social support for exercise from family and friends  54 |
| Miller et al. (2002) 33 (group 3) | Short-term effect | 1. ‘Formative research’  
2. Behaviour change strategies  
3. Evidence-based  
   - Community-wide PA interventions; targeting multiple levels of influence | A brochure with pros and cons and strategies to overcome barriers to PA identified by mothers  
   - See Miller group 2  
   - Discussion groups to explore barriers to PA that formed basis for the development of intervention strategies  
   - E.g. walking groups that met immediately after delivering children to the child care centre; sharing knowledge of existing services in the local area; many active women invited other mothers to join them in their activities such as a tennis group in which women rotated playing tennis and child care  
   - E.g. project staff lobbying local leisure-service providers to include or improve child care services and to make their timetable of activities more ‘mom-friendly’ (e.g. scheduling aqua-aerobics classes at the same time as children’s learn-to-swim classes) | Mediation  
   - Results suggest that partner support and self-efficacy were acting as mediators of PA behaviour change resulting from the intervention |

| Miller et al. (2002)\[34\] (group 2) | Short-term effect | 1. Behaviour change strategies  
- EDU | A brochure with pros and cons and strategies to overcome barriers to PA identified by mothers  
- Group 2 and 3: A booklet containing information about the benefits of PA, and strategies for overcoming barriers that are specific to mothers of young children | No mediation  
- Residual change in self-efficacy was negative in both groups 1 and 2 |
| Watson et al. (2005)\[35\] | Short-term effect | 1. Behaviour change strategies  
- GP, EDU (optional) | Walking groups to overcome barriers of mothers to PA  
- Pram walking to overcome the barriers to PA of child care, cost, time and social isolation  
- Pram walking routes taking into consideration: width and condition of the path; road crossings on route; accessibility by public transport; aesthetic nature of route; presence of clean toilets and shade or shelter with a seat for feeding, preferably at starting point | Process evaluation: appreciation of pram walking  
- Mothers emphasized the importance of walking routes that met the needs of women with babies and young children  
- The majority of mothers joined a pram walking group for exercise, to get out of the house and meet other postpartum women |

General: PA, physical activity; F&V, fruit and vegetables; %E, percentage of energy; TV, television; PAR, 7 d Physical Activity Recall; SES, socio-economic status; WIC, Special Supplemental Nutrition Program for Women, Infants, and Children.  
Behaviour change strategies: EDU, education; PC, discussing pros and cons; SS, providing/building social support; PE, peer educator; GP, guided practice; GS, goal setting; RF, reinforcement; DS, discussing strategies to overcome barriers; ST, skill training; INC, incentives; ML, modelling; FB, feedback; SM, self-monitoring; CB, capacity building.
analyses based on race, education, parity or BMI category in one study. Both studies of Havas et al. found that mothers younger than 30 years and with at least high-school education showed significantly greater increases in healthy eating. One study also found this pattern for married and non-working women. Furthermore, white women showed significantly greater increases in fruit and vegetable consumption in one study, while in the other study significant changes in healthy eating were found in both black and white participants.

Of the three studies measuring long-term results (7 months to 1 year), only Havas et al. reported long-term nutritional behaviour change. Henceforth, the description of the results will focus on short-term effects since these are available for all studies.

**Components within interventions which resulted in significant vs. non-significant effects**

More systematically developed interventions were more likely to be effective (Table 5). Four interventions were developed using less than three out of five key components of a systematic development (i.e. formative research, theory-based, behaviour change strategies, evidence-based or targeted to socio-economic status/ethnicity), none resulting in significant effects. Of the other eight interventions using three key components or more, six interventions appeared to be effective in changing physical activity and healthy eating positively. Of the seven interventions directed at promoting healthy eating, three showed positive statistically significant results, of which only one was targeted at motivations of mothers. The motivational appeals regarded 'set a good example for your children' and 'take care of yourself by eating more fruits and vegetables also after pregnancy'. In addition, more general behavioural change strategies such as the use of peer educators and role modelling were used in order to promote healthy eating.

In contrast, all eight interventions trying to promote physical activity included components targeted at mothers; mostly at overcoming barriers specific for mothers (e.g. physical changes, lack of time, social support or energy; Table 3). Five studies with components targeted at mothers did not show significant results on physical activity. Of these studies, three were aimed at multiple behaviour change. The two other interventions consisted of a single intervention; a brochure with tips for how to overcome barriers or exercise – pram walking – groups. These components were also elements in the three studies that showed significant results on physical activity. For example, exercise classes were organized and brochures were used with tips including how to overcome mother-specific barriers. However, these studies had additional (targeted) components (i.e. were multi-component) to promote physical activity (as a single behaviour). Both Cramp and Brawley and Fahrenwald used in addition interactive counselling about perceived barriers and making plans on how to overcome these barriers. Furthermore, in the group III intervention of Miller et al. intervention mothers were asked to participate in discussion groups to explore their perceived barriers for physical activity. Outcomes formed the basis for the development of intervention strategies.

**Explanations for effectiveness derived from additional analyses**

Some studies investigated, and mostly found, evidence for the influence of effective interventions through mediators (mainly social support and self-efficacy) and attendance on physical activity or healthy eating (Table 5). In addition, Leemakers et al. analysed the influence of adherence. The number of self-monitoring records returned was found to be significantly correlated with weight loss. Homework completion or telephone contact was not found to be associated with greater changes. No studies evaluated the targeted intervention components in relationship with effectiveness on physical activity. Regarding targeting, only the perception of pram walking groups by mothers was investigated in one study. Mothers emphasized the importance of having walking routes that met the needs of women with babies and young children. The majority of mothers who joined a pram walking group did so for exercise, to get out of the house and to meet other young mothers.

**Discussion**

The aim of the present review was to gain insight into targeted intervention components which may contribute to the attendance and effectiveness of interventions promoting physical activity and/or healthy eating to mothers with young children. Six out of the twelve studies included here measured attendance, of which two reported a high attendance. Especially the embedding of the intervention in routine visits to child health clinics seems to increase attendance rates. Cited explanations for non-attendance were general as well as mother-specific factors such as lack of interest, withdrawal from intervention setting and conflicting schedules.

Moreover, only six of the interventions reported statistically significant effects. Of these, three studies found positive effects on physical activity and three on healthy eating. Effective interventions directed at physical activity were multi-component and included such elements as counselling on mother-specific barriers or community involvement in intervention development and implementation. Interventions that effectively increased healthy eating did not all have components targeted at mothers. Only one study used mother-specific motivational appeals to promote healthy eating. No studies evaluated the targeted intervention components in relationship with effectiveness of the intervention in particular.
Targeting interventions at mothers

The low attendance reported for most of the interventions shows the difficulty of reaching mothers of young children in programmes for promoting health behaviours — as mentioned by other authors(31,33,34,41,42). This is also reflected in the large number of attempts to increase attendance with only minor results. For example, in spite of the fact that lack of time is frequently found to be a major barrier for mothers(43), targeted intervention components such as repeated intervention sessions to overcome scheduling problems did not result in high attendance rates. This may be due to the fact that underlying factors causing time constraints among mothers are neglected in such a strategy (see also Watson et al.(35)). In a survey by Brown et al.(36), mothers mostly reported that having no time was due to commitments to children, housework and shopping. This may originate in restrictive role expectations towards mothers and the mother’s perception of ‘being a good mother’(17,44). Strategies that take these factors into account may provide opportunities for promoting attendance.

Furthermore, childcare responsibilities and costs have been identified by mothers as two important barriers for attending weight-loss interventions(43,45). However, studies that solved the problem of child care and had no costs did not consistently result in high attendance(25,35,36). This may be due to a lack of interest for lifestyle change on the part of mothers. In a previous qualitative study investigating perceived barriers to attend weight-loss programmes, in addition to costs and child care, disinterested mothers perceived lack of time, family duties and conflicts with working schedule as barriers more compared with interested mothers(43). In intervention studies with no costs and solutions for child care, indeed a lack of interest was mentioned as one of the reasons for a low attendance by actively recruited participants(25,37). While another study with no costs and need for child care achieved a high attendance; in that study participants were recruited passively and thus were more likely to be highly motivated(40). Therefore, motivating mothers, for example through mass media campaigns in order to get them physically active or eat healthier, seems a worthwhile point for reaching more mothers. Since the well-being of children is very important to mothers(17), emphasizing that mothers are role models for their children might increase interest.

Because the well-being of children is important to mothers, it is reasonable that an intervention setting for the good of children will increase attendance. This is supported by the study of Kinnunen et al.(33), whereby an intervention was embedded within routine visits to child health clinics resulting in a high attendance. Embedding the intervention in the routine of mother and child also gets round the problems of lack of time and child care responsibilities. Two other studies showed, however, that embedding the intervention within mothers’ routine visits to an intervention setting might not contribute to attendance when there is withdrawal from this setting(25,30).

With regard to the question on which intervention components contribute to the effectiveness on behaviour change, we found that all reviewed physical activity interventions included components targeted at mothers with young children. For physical activity, interactive counselling or discussion sessions about social and practical barriers perceived by mothers and making plans on how to overcome these barriers within the individual environment(32,36) or local community settings(34) seems to promote physical activity among mothers. Such a strategy can address important constraints frequently cited by mothers, such as lack of time, energy, child care and social support, and obligations to other roles(30).

Only one of the interventions aimed at improving healthy eating had components targeted towards mothers, while three out of four studies aimed at promoting healthy eating as a single behaviour showed statistically significant results. This one study used mother-specific motivational appeals rather than targeting mother-specific barriers. This may be because changing dietary behaviour is easier for mothers when compared with changing their physical activity pattern. In a previous study, young adult women reported that they saw a whole range of healthy eating behaviours as highly feasible but not many physical activity behaviours(46). Mothers did perceive fruit and vegetable consumption to be more feasible compared with non-mothers although they perceived leisure-time physical activity, physical activity for transport purposes and incidental physical activity as less feasible compared with women with no children.

Definite conclusions about which components may contribute to intervention effectiveness cannot be drawn; however, from the studies included in the current review since the actual contribution of components targeted at mothers of young children on the effectiveness has not been evaluated. Only the appreciation of pram walking groups was found by Watson et al.(35). Therefore, the effectiveness on physical activity and on healthy eating may also depend on the multi-component character or the systematic development of most of the effective interventions included in the review. Furthermore, theory-based developed interventions aimed at reaching intervention effects on physical activity or healthy eating through theoretical constructs (i.e. mediators) that are important for mothers, such as self-efficacy and social support, might increase effectiveness(34,39,40). There is a need for more process evaluations which focus on the question of how intervention effects are obtained.

Furthermore, in order to disseminate the use of interventions, it is necessary to know to which subpopulations the programme effects can be generalized. Notable was that while all studies with mainly low-income or ethnic minority participants in the present review had targeted their interventions to these low-income and/or minority groups(25,26,29,30,32), only two studies performed subgroup analyses(25,30). More of such analyses are needed to gain insight into the effectiveness of interventions for specific
target groups. In accordance, future studies that conduct subgroup analysis for mothers: non-mothers can give more information about the generalizability of interventions directed at women in general towards mothers in particular.

The main limitations of the present review study are the limited amount of eligible studies found, that information-gathering was restricted to printed material, and the low comparability of the studies. For instance, studies differed on the quality of design, sample size and outcome measurements. For this reason, the choice for descriptive analyses was made and no meta-analyses could be done. Nevertheless, these descriptive analyses can be useful for intervention practice since they could provide examples for future intervention development and implementation. For health promotion, it might be worthwhile also to include study designs other than randomized controlled trials (i.e., true experiments) in a review. The use of randomized controlled trials is not always appropriate to evaluate health promotion interventions; consequently reviewing interventions evaluated in other designs such as quasi-experiments can be more applicable for practice.

Conclusions

Although promoting weight control among new mothers is valuable in obesity prevention, the number of experimental intervention studies for promoting physical activity and healthy eating among new mothers is limited. Nevertheless, first recommendations useful for intervention practice can be set. Opportunities for increasing attendance of future interventions directed at mothers are, for example, embedding interventions into the mother and child routine, addressing the restricting role expectations for mothers, or motivating mothers for lifestyle change activities first. In addition, systematic development and multi-component interventions seem important to the success of these interventions. Moreover, chances for promoting physical activity among mothers are targeting the methods used regarding mother-specific barriers. Little evidence is found yet, however, to suggest the need for and recommend ways of targeting at new mothers for stimulating healthy eating. More research is required to substantiate the findings, especially with regard to the promotion of healthy eating. Process and subgroup analyses can contribute more insight into how interventions work and for which subgroups.
