PAT MORIN,*** Carleton University

Abstract
Motivated by applications of Gabriel graphs and Yao graphs in wireless ad-hoc networks, we show that the maximum degree of a random Gabriel graph or Yao graph defined on n points drawn uniformly at random from a unit square grows as Θ(log n / log log n) in probability.

Keywords: Random geometric graph; Gabriel graph; Yao graph; maximum degree

2000 Mathematics Subject Classification: Primary 60D05

1. Introduction

Wireless ad-hoc networks consist of computers (or sensors) capable of communicating wirelessly with each other without any centralized information, infrastructure, or organization. A common mathematical model of such networks is the unit disk graph, in which the nodes consist of n points in R² and an edge exists between two nodes if and only if the distance between them is at most r. Depending on the value of r, which represents the transmission range of the wireless transmitters, the network can be anything ranging from a set of isolated vertices to the complete graph. The unit disk graph is also the basic model of continuum percolation theory [14].

The lack of centralized management and organization that occurs in ad-hoc networks means that individual nodes in the network typically have only local information about the nodes that they can communicate directly with. This makes even basic tasks, such as routing, highly nontrivial because the combination of complete lack of organization and the unit disk graph topology is too unwieldy.

One approach to taming ad-hoc networks has been to compute the intersection of the unit disk graph with some ‘nice’ proximity graph, where the intersection of two graphs, G₁ = (V, E₁) and G₂ = (V, E₂), is the graph (V, E₁ ∩ E₂). If the right proximity graph is chosen, the resulting graph will remain connected (if the original unit disk graph is connected) and will inherit some of the nice properties of the proximity graph. Ideally, the intersection can be computed locally, so that individual nodes can locally determine which of their incident edges belong to the intersection.

One such approach computes the intersection of the unit disk graph with the Gabriel graph [8]. The Gabriel graph contains an edge between two points $u$ and $v$ if and only if the disk whose diameter is $\|uv\|$ contains $u$ and $v$ on its boundary and no points other than $u$ and $v$ (see Figure 1). The Gabriel graph is planar and, therefore, has only a linear number of edges. Algorithms for routing on planar graphs can be applied to the resulting graph or, more commonly, these algorithms can be used for recovery when routing heuristics fail. A number of routing algorithms and protocols have been proposed based on this strategy [2], [4], [11].

Another suggested approach uses the Yao graph [25]; see Figure 2. Let $p$ be a positive integer, let $\theta = 2\pi/p$, and let $u$ be a point in $\mathbb{R}^2$. The $i$-cone of $u$ is the set of all points $w \in \mathbb{R}^2$ such that the angle $\angle quw \in (\,(i-1)\theta, i\theta\,)$, where $q = u + (1, 0)$. The $\theta$-Yao graph contains an edge from $u$ to the nearest point in each of $u$’s $i$-cones for $i = 1, \ldots, p$. For any constant $p \geq 6$, the $\theta$-Yao graph has at most $pn$ edges and is a spanner; for any two vertices $u$ and $v$, the $\theta$-Yao graph contains a path whose Euclidean length is at most $t\|uv\|$, where $\|uv\|$ denotes the Euclidean distance between $u$ and $v$, and $t = 1/(1 - 2\sin(\theta/2))$ is called the stretch factor. When applied in the context of unit disk graphs, if there is a path of Euclidean length $\|uv\|$ in the original unit disk graph, then there is a path of length at most $t\|uv\|$ in the intersection

of the unit disk graph and the \( \theta \)-Yao graph. Routing strategies based on the Yao graph attempt to find power-efficient routing paths \([10], [12], [18], [24]\).

### 1.1. New results

Motivated by the above applications in wireless networks, in the current paper we study the Gabriel graph and Yao graph of \( n \) points uniformly and independently distributed in a unit square. This distribution assumption can be used to approximately model the unorganized nature of ad-hoc networks and is commonly used in simulations of such networks \([19]\). Additionally, some types of sensor network, especially with military applications, are specifically designed to be deployed by randomly placing (scattering) them in the deployment area. This distribution assumption models these applications very well.

We show that the maximum degree of any node in a Gabriel graph or a Yao graph is concentrated at \( \Theta \left( \frac{\log n}{\log \log n} \right) \). (Throughout this paper \( \log x \) denotes the natural logarithm of \( x \).) More specifically, if \( \Delta \) is the maximum degree of either graph then we show that there exist constants \( a \) and \( b \) such that

\[
\lim_{n \to \infty} \Pr \left\{ \Delta \in \left[ \frac{a \log n}{\log \log n}, \frac{b \log n}{\log \log n} \right] \right\} = 1.
\]

For Gabriel graphs, we show this for \( (a, b) = \left( \frac{1}{12}, 1 \right) \) and, for Yao graphs, we show it for \( (a, b) = \left( \frac{1}{8}, 4 \right) \). The maximum degree is particularly important in wireless networks, since the degree of a node directly impacts the amount of bookkeeping the node must do. With wireless nodes typically being battery operated and often memory and computationally constrained, the degree of a node should hopefully be as small as possible in order to minimize this bookkeeping.

### 1.2. Related work

The monograph by Penrose \([16]\) presented a comprehensive treatment of the properties of unit disk graphs of points uniformly distributed in \([0, 1]^d\), including connectivity, minimum and maximum degree, maximum clique size, and a number of other parameters.

A random Gabriel graph in this paper is a Gabriel graph for \( n \) points drawn uniformly and at random from \([0, 1]^d\). Its key properties were studied in great depth by Matula and Sokal \([13]\). For example, the expected number of edges grows as \( 2^{d-1}n \) \([7], [13]\). The length of an edge taken at random from all edges has expected value and standard deviation \( \Theta \left( n^{-1/d} \right) \) \([7]\). These properties hold also for many nonuniform distributions \([7]\).

For a uniform Poisson process, introduced to avoid edge effects, Bern et al. \([3]\) showed that the expected value of the maximum degree of a Delaunay triangulation grows as \( \Theta \left( \log n / \log \log n \right) \). For that model, their proof also worked for Gabriel graphs. It is known that the Gabriel graph is a subgraph of the Delaunay triangulation (see \([20]\)), so our upper bound on the maximum degree in a Gabriel graph would in fact follow without too much work from the cited paper. Our work on Gabriel graphs differs in three aspects.

1. We show convergence in probability. The fact that the expected maximum degree grows as \( \Theta \left( \log n / \log \log n \right) \) does not imply that the probability of obtaining such large maximum degrees tends to 1. We show that it does.

2. We deal with a fixed sample size model on a unit square, not the Poisson model on the entire plane.

3. Our proofs are different.
The relative neighborhood graph is obtained by joining all pairs whose loon is empty, where the loon defined by a pair is the intersection of two spheres of equal radius, each having one point as its center and the other point on its surface (see [21]). As it is a subgraph of the Gabriel graph, our results imply that its maximum degree is $O(\log n / \log \log n)$ in probability. For a general discussion of proximity graphs and their applications, we refer the reader to the survey papers by Toussaint [20], [22]. For an application of the relative neighborhood graph to wireless networks, see [11].

To the best of the authors’ knowledge, random Yao graphs have not been studied previously. Although researchers have been interested in spanners having small maximum degree (see the textbook by Narasimhan and Smid [15, Chapters 4 and 8] for a survey), most research in this area has been on constructing spanners that have low degree in the worst case. Some of these constructions have been adapted for use in the unit disk graph model of wireless networks [23], but the computation of these spanners is not quite as straightforward and local as that of Yao graphs.

The remainder of this paper is organized as follows. In Section 2 we present our results on Gabriel graphs. In Section 3 we present our results on Yao graphs. Each of these sections concludes with a summary and discussion of possible generalizations and limitations.

### 2. Gabriel graphs

In this section we prove bounds on the maximum degree of vertices in a Gabriel graph. Before we begin, we discuss an equation that is central to all our upper and lower bounds, as well as many other bounds of this type.

Let $c > 0$ be a constant, and let $k = c \log n / \log \log n$. In all our bounds, the value $k^k$ appears at some point in the computations. Note that

$$k^k = n^{k(1+\log c - \log \log n)/\log \log n} = n^{c - o(1)}.$$  \hspace{1cm} (2.1)

In particular, $k = O(n^c)$ and, for any $\varepsilon > 0$, $k = \Omega(n^{c-\varepsilon})$.

#### 2.1. A lower bound

In this section we prove the following result.

**Theorem 2.1.** For a random Gabriel graph defined on $n$ points drawn independently from the uniform distribution on $[0, 1]^2$,

$$\lim_{n \to \infty} \Pr\left\{ \text{maximum degree} < \frac{c \log n}{\log \log n} \right\} = 0$$

for all $c < \frac{1}{12}$.

**Proof.** We start with a technical construction of a region and then a point configuration. This construction is parameterized by an integer $k$ and a positive number $r$. Define the angle $\xi = 2\pi/(3k)$, and partition the plane into $3k$ sectors of angle $\xi$ each, with center at the origin. We refer the reader to Figure 3 for further explanations.

Draw two concentric circles, both centered at the origin, of radii $r$ and $R$ with $R > r$, so that $r = R \cos \xi$. If the sectors are numbered $C_1, C_2, \ldots, C_{3k}$ (clockwise) and the circles are $S_r$ and $S_R$, then we mark $k$ regions (shown in dark gray in Figure 3). These regions are of the form $(S_R \setminus S_r) \cap (C_{3i+1} \cup C_{3i+2})$ for $0 \leq i \leq k-1$. Call these regions pearl regions and denote...
them by $P_1, \ldots, P_k$. Any circle with its diameter being the segment linking the origin with any point in a pearl region totally avoids any other pearl region. To see this, refer to Figure 3 and recall that $r = R \cos \xi$.

Assume that we are given $m$ points in the plane, $x_1, \ldots, x_m$, and a center $x$. If $x + A$ denotes the translate of a set $A$ by $x$ then we call $x$ a $(k, r)$-tiara for $x_1, \ldots, x_m$ if exactly $k$ of the points $x_i$ fall in $x + S_R$, and if each set $x + P_j$ covers exactly one of these $x_i$s. See Figure 4. If we construct the Gabriel graph for $x, x_1, \ldots, x_m$ then the degree of the vertex at $x$ is at least $k$ if $x$ is a $(k, r)$-tiara for $x_1, \ldots, x_m$. 

Figure 3: The definition of a pearl.

Figure 4: The shaded regions define a $(7, r)$-tiara.
The above construction and definitions are for any point sets. Assume that a random sample of size $n$ is drawn from the uniform distribution on $[0, 1]^2$, and denote it by $X_1, \ldots, X_n$. Define $k = \max(3, \lfloor c \log n / \log \log n \rfloor)$ and $r = 1/\sqrt{n}$. We say that $X_i$ is a jewel if $X_i$ is a $(k, r)$-tiara for $\{X_j : j \neq i\}$ and if $X_i$ is a distance at least $2r$ from the perimeter of $[0, 1]^2$. Note that $R \leq 2r$, so that $X_i + P_j \subseteq [0, 1]^2$ for all $j$.

We compute the probability that $X_1$ is a jewel given $X_1 = x$, provided that $x$ is a distance at least $2r$ from the perimeter of the unit square. Note that this probability may be written as a multinomial probability. If $p$ is the area of $x + P_j$, we have, in particular,

$$
\Pr[X_1 \text{ is a jewel } | X_1 = x] = \frac{(n-1)!}{(n-1-k)!} p^k (1 - \pi R^2)^{n-1-k} \\
= \frac{(n-1)!}{(n-1-k)!} p^k \left(1 - \frac{\pi}{n \cos^2 \xi}\right)^{n-1-k} \\
\geq \frac{(n-1)!}{(n-1-k)!} p^k \left(1 - \frac{2\pi}{n}\right)^{n-1-k} \quad \text{(since } \xi \leq 2\pi/9 < \pi/4) \\
\geq (n-k)^k p^k \left(1 - \frac{2\pi}{n}\right)^n \\
\geq (n-k)^k p^k (\frac{1}{3})^{2\pi}.
$$

As $k \geq 3$, we have $\xi \leq 2\pi/9 < 1$, so that $\tan \xi \geq \xi$. Therefore,

$$
p = (R^2 - r^2)\xi = R^2 \xi \sin^2 \xi = r^2 \xi \tan^2 \xi \geq \frac{\xi^3}{n}.
$$

Resubstitution yields

$$
\Pr[X_1 \text{ is a jewel } | X_1 = x] \geq (n-k)^k \frac{\xi^3}{n^k} \left(\frac{1}{3}\right)^{2\pi} \\
= \left(1 - \frac{k}{n}\right)^k \left(\frac{1}{3}\right)^{2\pi} \xi^{3k} \\
= \left(1 - \frac{k}{n}\right)^k \left(\frac{1}{3}\right)^{2\pi} \left(\frac{2\pi}{3}\right)^{3k} \\
\geq k^{-3k}
$$

when $n$ is large enough, uniformly over all $x$ a distance at least $2r$ from the perimeter of the unit square. We may now unconditional. If $N$ is the number of jewels among the data points, we have

$$
\mathbb{E}[N] = n \Pr[X_1 \text{ is a jewel}] \geq n(1 - 4r)^2 k^{-3k} \sim nk^{-3k}.
$$

If $k$ is as we picked it, and $c < \frac{1}{4}$, then $\mathbb{E}[N] \to \infty$. This is not quite enough to show that $\Pr[N > 0] \to 1$. There are several routes we can follow at this point: we could Poissonize the sample size; we might redefine jewels so that at most one jewel occurs in any region of a regular grid. Both tricks create enough independence to get by. Instead, we opt to use the second moment method (for references, see [1, Chapter 4]). When applied to a counting random variable $N = \sum_{i=1}^n Y_i$, where the $Y_i$s are $\{0, 1\}$-valued with a permutation-invariant joint distribution, the second moment method implies that $N/\mathbb{E}[N] \to 1$ in probability whenever $\mathbb{E}[N] \to \infty$ and

$$
\lim_{n \to \infty} \sup \frac{\mathbb{E}[Y_1 Y_2]}{\mathbb{E}[Y_1] \mathbb{E}[Y_2]} \leq 1.
$$
In our case we only need to verify the latter condition when $Y_i$ is the indicator that $X_i$ is a jewel, so that $N$ is the number of jewels. Let $A$ be the event that $X_1$ or $X_2$ is within $2r$ of the perimeter of the unit square, or that $||X_1 - X_2|| \leq 4r$. On $A^c$, the complement of $A$, we have, by the multinomial argument given above, but now applied to two tiaras,

$$E[Y_1 Y_2 | A^c] = \frac{(n - 2)!}{(n - 2 - 2k)!} p^{2k} (1 - 2\pi R^2)^{n-2-2k},$$

where $p$ is the area of a pearl region $P_j$. We recall that

$$E[Y_1] \geq \frac{(n - 1)!}{(n - 1 - k)!} p^k (1 - \pi R^2)^{n-1-k} \geq k^{-3k}$$

for large enough $n$. Thus, for such large $n$,

$$\frac{E[Y_1 Y_2]}{E[Y_1] E[Y_2]} = \frac{Pr[A] E[Y_1 Y_2 | A]}{E[Y_1] E[Y_2]} + \frac{Pr[A^c] E[Y_1 Y_2 | A^c]}{E[Y_1] E[Y_2]}$$

$$\leq \frac{Pr[A]}{E[Y_1] E[Y_2]} + \frac{Pr[A^c]}{E[Y_1] E[Y_2]} + \frac{(n - 2)!}{(n - 2 - 2k)!} p^{2k} (1 - 2\pi R^2)^{n-2-2k}$$

$$\times \frac{(n - 1 - k)!^2}{(n - 1)^2} p^{-2k} (1 - \pi R^2)^{2k+2-2n}$$

$$\leq \frac{67}{n^{1/2} k^{-6k}} + 1 + O\left(\frac{k^2}{n}\right).$$

We are done if $n^{1/2} k^{-6k} \to \infty$. For this, in the definition of $k$, we need only pick $6c < \frac{1}{2}$, or $c < \frac{1}{12}$. We have thus shown that $N/E[N] \to 1$ in probability when $c < \frac{1}{12}$ in the definition of $k$. We conclude that $Pr[N = 0] \to 0$ for such choices of $c$. Therefore,

$$\lim_{n \to \infty} Pr\left\{ \text{maximum degree in Gabriel graph} < \frac{c \log n}{\log \log n} \right\} = 0$$

for all $c < \frac{1}{12}$.

2.2. An upper bound

**Theorem 2.2.** For a random Gabriel graph defined on $n$ points drawn independently from the uniform distribution on $[0, 1]^2$,

$$\lim_{n \to \infty} Pr\left\{ \text{maximum degree} > \frac{c \log n}{\log \log n} \right\} = 0$$

for all $c > 1$.

**Proof.** At a point $x$, partition the space into $k$ equal sectors each having their apex at $x$ and of angle $2\pi/k$ each, where $k = \lceil \sqrt{\log n} \rceil$. Within each sector, we color the point nearest to $x$ red. If a sector has a red point $y$, consider the perpendicular line at $y$ to the segment $(y, x)$ and call this line the separator. All points in the same sector, on the same side of the separator as $x$ are colored blue. In Figure 5, these are precisely the points that fall in the shaded wedges.
We first claim that each Gabriel graph neighbor of \( x \) is colored red or blue. Indeed, any point \( y \) excludes all points at the other side of the separator—the side that does not contain \( x \). Thus, if there is a red point in the sector, only blue points can possibly be Gabriel neighbors of \( x \). Let \( r = 3\sqrt{\log n / n} \) and recolor any (blue or red) point \( z \) to be yellow if it is a Gabriel neighbor of \( x \) and \( \|xz\| > r \).

Figure 6 shows several points with their separators. No point in the shaded area can be a Gabriel neighbor of the point \( x \) at the origin. Note that, for every point in the shaded area, the Gabriel circle through the origin contains another point. Figure 7 shows several sectors and red points, together with the wedges in which blue points must fall. The angle of each sector is \( \theta = 2\pi / k \).

Let \( N_r \), \( N_b \), and \( N_y \) be the total number of red, blue, and yellow points, respectively. Recall that \( k = \lceil \sqrt{\log n} \rceil = o(\log n / \log \log n) \), so \( N_r \leq k = o(\log n / \log \log n) \). Also, conditioning
on $X_1 = x$,

$$E[N_y \mid X_1 = x] = n \Pr\{X_2 \text{ is a Gabriel neighbor of } X_1, \|X_2 - X_1\| \geq r \mid X_1 = x\}$$

$$\leq n(1 - \pi (r/2)^2 / \pi)^{n-1}$$

(because at least a $\frac{1}{4}$ fraction of the Gabriel circle through $x$ and $X_2$ falls in the unit square)

$$\leq n(1 - r^2 / 4)^{n-1}$$

$$\leq ne^{-9(n-1) \log n / (4n)}$$

$$\sim n^{1 - 9/4}$$

$$\rightarrow 0.$$

Thus, it suffices to study $N_b$.

As $\tan \theta \leq \theta + \theta^3$ for $0 \leq \theta \leq 1$, the area of each wedge is at most

$$\frac{r^2}{2} (\tan \theta - \theta) \leq \frac{9 \log n \theta^3}{2n}$$

$$\leq \frac{72 \log n \pi^3}{2nk^3}$$

$$\leq \frac{1200 \log n}{nk^3}.$$ 

The total wedge area around $X_1 = x$ is thus not more than

$$\frac{1200 \log n}{nk^2} \leq \frac{1200}{n}.$$
Given $X_1 = x$ and the collection of red points, the $n - 1 - N_r$ other points are uniformly distributed on the unit square, but not in any of the $N_r$ circular sectors just inside the wedges, and not in any circular sectors of radius $r$ defined when no red point is present in the sector. Call the density $f$ and its support set $S$. Clearly, $1 \leq f \leq 1/(1 - \pi r^2)$. Of the $n - 1 - N_r$ points, let $M$ denote the total number of points falling in the wedges. Clearly, $M$ is stochastically smaller than a binomial random variable with parameters $m = n - 1 - N_r$ and $p = 1200/n(1 - \pi r^2)$.

In particular, using $l! \geq (l/e)^l$, and letting $Pr$ denote the conditional probability,

$$Pr\{M \geq l\} \leq \sum_{j=l}^{m} \binom{m}{j} p^j (1 - p)^{m-j}$$

$$\leq \sum_{j=l}^{\infty} \frac{(mp)^j}{j!}$$

$$= \frac{(mp)^l}{l!} \sum_{j=0}^{\infty} \frac{(mp)^j}{(l+j)!}$$

$$\leq \frac{(mp)^l}{l! (1 - mp/l)}$$

$$\leq \frac{(npe/l)^l}{l! (1 - mp/l)}$$

We set $l = \lceil c \log n / \log \log n \rceil$ for a constant $c$ and note that $np/l = o(1)$. By the union bound, the probability that there exists a point $x$ for which the number of blue points in the wedge collection for $x$ is greater than or equal to $l$ does not exceed

$$n \times \frac{(npe/l)^l}{(1 - np/l)}.$$

As $np = 1200 + o(1)$, the above expression is, for all large enough $n$, not more than $2n(3600/l)^l$. By (2.1), this tends to 0 when $c > 1$.

The probability that, for one of the data points, $N_y > 0$ is not more than

$$n \times (1 + o(1)) n^{1-9/4} \to 0.$$

Thus, we have shown that, for $c > 1$, the probability that the maximum degree exceeds $k + l$ tends to 0. As $k + l \sim l$, we are done.

### 2.3. Remarks

**Higher dimensions.** Just as Bern et al. [3] showed for the expected maximum degree in a Delaunay triangulation, the results of Theorems 2.1 and 2.2 extend easily to $\mathbb{R}^d$. In particular, for any $d$, there exist constants $a > 0$ and $b < \infty$ depending only upon $d$ such that

$$\lim_{n \to \infty} \Pr \left\{ \text{maximum degree} \geq \left( \frac{a \log n}{\log \log n}, \frac{b \log n}{\log \log n} \right) \right\} = 0.$$
Edge lengths. The results on $N_y$ in the proof above show that the expected number of Gabriel edges of length at least $3 \sqrt{\log n/n}$ is $o(1)$. Hence, the probability that the maximum edge length exceeds $3 \sqrt{\log n/n}$ tends to 0. Bounds on sums of functions of the edge lengths of random Gabriel graphs are given in [17].

3. Yao graphs

In this section we present our results on Yao graphs. For simplicity, we consider $\theta$-Yao graphs with $\theta = \pi/2$. The modifications required for other (smaller) values of $\theta$ are discussed at the end of this section. The lower bound in Section 3.1 is obtained using a construction and argument similar to the pearl used to prove Theorem 2.1. The upper bound in Section 3.2 uses different arguments based on maxima.

For the upper bound, we change the distribution model slightly by rotating it by $\pi/4$. More precisely, let $D^2$ denote the unit square rotated by $\pi/4$. The upper bound assumes that points are distributed uniformly and independently in $D^2$. At the end of this section, we discuss why this slightly different assumption is necessary.

3.1. A lower bound

Our lower bound argument is similar to that used for Gabriel graphs, in that we define a configuration of points whose existence implies a vertex of degree $k$ and show that, with high probability, this configuration exists in a random point set.

**Theorem 3.1.** For a random $\pi/2$-Yao graph defined by $n$ points drawn independently from the uniform distribution on $[0, 1]^2$,

$$\lim_{n \to \infty} \Pr \left\{ \text{maximum degree} < \frac{c \log n}{\log \log n} \right\} = 0$$

for all $c < \frac{1}{8}$.

**Proof.** Refer to Figure 8(a). Let $r > 0$ be a real number, and let $k$ be a positive integer. Define $k$ square regions $P_1, \ldots, P_k$, where

$$P_i = \left[ \frac{(i - 1)r}{k}, \frac{ir}{k} \right] \times \left[ r - \frac{ir}{k}, r - \frac{(i - 1)r}{k} \right].$$

These regions are called steps.

Assume that we are given $m$ points in the plane, $x_1, \ldots, x_m$, and a center $x$. Then we call $x$ a $(k, r)$-staircase for $x_1, \ldots, x_m$ if exactly $k$ of the points $x_i$ fall into the square $x + [-r, r]^2$ and if each step $x + P_j$ covers exactly one of these $x_i$s. If we construct the $\pi/2$-Yao graph for $x, x_1, \ldots, x_m$ and $x$ is a $(k, r)$-staircase for $x_1, \ldots, x_m$, then every point in each of the $k$ steps is adjacent to $x$, so $x$ is a vertex of degree at least $k$ (see Figure 8(b)).

Let $k = c \log n / \log \log n$, let $r = \sqrt{2/n}$, and let $X_1, \ldots, X_n$ be $n$ points drawn uniformly and independently from $[0, 1]^2$. Then the area, $p$, of a step in a $(k, r)$-staircase is...
\[ p = \left(\frac{r}{k}\right)^2 = \frac{2}{nk^2}, \]
so
\[ \Pr(X_1 \text{ is a } (k, r)-\text{staircase} \mid X_1 \in [r, 1-r]^2) = \frac{(n-1)!}{(n-k)!} \left(1 - \frac{8}{n}\right)^{n-k-1} \]
\[ \geq \left(1 - \frac{k}{n}\right)^k \left(1 - \frac{8}{n}\right)^{2k} \]
\[ \geq k^{-2k} \]
for sufficiently large \( n \). Thus, if \( N \) is the number of staircases among \( X_1, \ldots, X_n \) then
\[ \mathbb{E}[N] \geq n(1 - 2r)^2k^{-2k} = \Omega(n^{1-2c-r}) \to \infty, \]
provided that \( c < \frac{1}{2} \).
As before, we finish the proof using the second moment method. Let \( A \) denote the event that \( \{X_1, X_2\} \not\subset [r, 1-r]^2 \) or that \( X_2 \in X_1 + [-r,r]^2 \), and let \( A^c \) denote the complement of \( A \). Let \( Y_i, i \in \{1, 2\} \), denote the indicator variable that \( X_i \) is a staircase. Then, for sufficiently large \( n \),
\[ \frac{\mathbb{E}[Y_1] \mathbb{E}[Y_2]}{\mathbb{E}[Y_1] \mathbb{E}[Y_2]} \leq \frac{\mathbb{E}[Y_1 Y_2]}{k^{-4k}} \]
\[ = k^{4k} (\Pr[A] \mathbb{E}[Y_1 Y_2 \mid A] + \Pr[A^c] \mathbb{E}[Y_1 Y_2 \mid A^c]) \]
\[ \leq k^{4k} ((4r + 4r^2) + \Pr[A^c] \mathbb{E}[Y_1 Y_2 \mid A^c]) \]
\[ \leq k^{4k} (4r + 4r^2 + n^{-2} \left(\frac{1}{nk^2}\right)^{2k} \left(1 - \frac{16}{n}\right)^{n-2-2k}) \]
\[ \leq k^{4k} (4r + 4r^2 + n^2 \left(\frac{1}{nk^2}\right)^{2k} \left(1 - \frac{16}{n}\right)^{n-2-2k}) \]
\[ \leq k^{4k} \left(4 \sqrt{\frac{7}{n}} + \frac{8}{n}\right) + 1 \]
\[ = 1 + O(n^{4c-1/2}), \]
so \( \lim_{n \to \infty} \mathbb{E}[Y_1 Y_2]/\mathbb{E}[Y_1] \mathbb{E}[Y_2] = 1 \) for any \( c < \frac{1}{8} \).
3.2. An upper bound

Next we prove an upper bound on the maximum degree in a \((\pi/2)-Yao\) graph. The upper bound is based on the observation that the neighbors of a node in a Yao graph are so-called minima. Let \(x_1, \ldots, x_n\) be a set of points. We say that a point \(x_i\) dominates \(x_j\) if the \(x\) and \(y\) coordinates of \(x_i\) are larger than the \(x\) and \(y\) coordinates of \(x_j\), respectively. A point \(x\) is maximal with respect to \(x_1, \ldots, x_n\) if \(x\) is not dominated by any \(x_i\). A point \(x\) is minimal if \(x\) does not dominate any point \(x_i\).

Before we can present the upper bound, we require a few preliminary results about maxima and minima. First, though, we recall a classic result obtained using Chernoff’s bounding method [5].

**Lemma 3.1.** Let \(Y_1, \ldots, Y_m\) be a sequence of independent \(\{0, 1\}\)-valued random variables, let \(Y = \sum_{i=1}^{m} Y_i\), and let \(\mu = E[Y]\). Then, for any \(\delta > 0\),

\[
\Pr\{Y > (1 + \delta)\mu\} \leq \left(\frac{e^{\delta}}{(1 + \delta)^{1+\delta}}\right)^{\mu}.
\]

The following result is already quite well known. We include a proof sketch only for the sake of completeness.

**Lemma 3.2.** Let \(X_1, \ldots, X_m\) be a sequence of points drawn independently and uniformly from a rectangle \([a, b] \times [c, d]\) having area greater than 0, and let \(M\) be the number of maximal (or minimal) points among \(X_1, \ldots, X_m\). Then, for any \(\delta > 0\),

\[
\log m \leq E[M] \leq \log m + 1
\]

and

\[
\Pr\{M > (1 + \delta) E[M]\} \leq \left(\frac{e^{\delta}}{(1 + \delta)^{1+\delta}}\right)^{\log m}.
\]

**Proof.** Sort the elements of \(X_1, \ldots, X_m\) by decreasing \(x\) coordinate, so that \(X_i\) is maximal if and only if its \(y\) coordinate is the maximum among the \(y\) coordinates of \(X_1, \ldots, X_i\). Let \(Y_i = 1\) if \(X_i\) is maximal and \(Y_i = 0\) otherwise. Obviously, \(E[Y_i] = 1/i\), so

\[
E[M] = E\left[\sum_{i=1}^{m} Y_i\right] = \sum_{i=1}^{m} \frac{1}{i}.
\]

The inequality \(\log m \leq E[M] \leq \log m + 1\) is then obtained by bounding the above harmonic sum using the integral \(\int_{1}^{m} 1/x \, dx\) (see, e.g. [6, Appendix A.2]).

To prove the second part of the lemma, we use the fact that the random variables \(Y_1, \ldots, Y_m\) are independent [7], [9]. The result then follows immediately from Lemma 3.1.

Unfortunately, the points we consider will not always be drawn from a rectangle. A \(t\)-shape is a closed maximal subset of \(\mathbb{R}^2\) that is bounded by the \(x\) and \(y\) axes and a \(y\)-monotone polygonal path consisting of at most \(t\) edges (a piecewise-linear function of \(y\) having at most \(t\) pieces). See Figure 9(a).

**Lemma 3.3.** Let \(X_1, \ldots, X_m\) be a sequence of points drawn independently and uniformly from a \(t\)-shape \(S\) having area greater than 0, and let \(M\) be the number of minimal points among \(X_1, \ldots, X_m\). Then, for any \(\delta > 0\),

\[
E[M] \leq 2t(\log m + 1)
\]
We now have all the tools required to prove our upper bound.

**Theorem 3.2.** For a random \((\pi/2)\)-Yao graph defined on \(n\) points drawn independently from the uniform distribution on \(\mathbb{D}^2\),

\[
\lim_{n \to \infty} \Pr \left\{ \text{maximum degree} > \frac{4c \log n}{\log \log n} \right\} = 0
\]

for all \(c > 4\).

**Proof.** Let \(X_1, \ldots, X_n\) be points uniformly and independently distributed in \(\mathbb{D}^2\), and let \(G\) be the \((\pi/2)\)-Yao graph of \(X_1, \ldots, X_n\). Let \(\ell = \sqrt{d \log n/\log n}\). We will first consider the edges of \(G\) whose length is at most \(\ell\). Consider the square \(S = X_1 + [0, \ell]^2\), which contains all

---

**Figure 9:** (a) A \(t\)-shape \(S\). (b) Covering \(S\) to obtain a shape \(S'\) and uniformly distributing points in \(S'\). (c) Reflecting the points in \(S'\) to obtain points uniformly distributed in \(S\).
neighbors of \( X_1 \) in \( X_1 \)'s 1-cone. Let \( N \) denote the number of points of \( X_2, \ldots, X_n \) contained in \( S \). Then \( E[N] \leq n \ell^2 = d \log n \) and, by Lemma 3.1,

\[
\Pr[N > 2d \log n] \leq \left( \frac{e}{4} \right)^{d \log n} = n^{d(1-\log 4)}.
\]

Let \( N' \) denote the number of points in \( S \) that are neighbors of \( X_1 \) in the Yao graph. Each such point is minimal with respect to the \( N \) points of \( X_2, \ldots, X_n \) contained in \( S \). Furthermore, \( S \cap D^2 \) is a \( t \)-shape for \( t \leq 2 \). By the first part of Lemma 3.3, conditioned on \( N \leq 2d \log n \), the expected number of minimal points, and, hence, the number of neighbors of \( X_1 \) in \( S \), is small:

\[
E[N' \mid N \leq 2d \log n] \leq 4(2d \log n) + 1 = 4 \log n + \Theta(1).
\]

Define \( v = \log(2d \log n) \) and let \( k = (c \log n)/(\log \log n) \). By the second part of Lemma 3.3, with \( t = 2 \),

\[
\Pr[N' > k \mid N \leq 2d \log n] = \Pr\left\{ N' > \frac{c \log n}{\log(2d \log n)} (4v + 1) \mid N \leq 2d \log n \right\}
\leq 4 \left( \frac{f(n)}{g(n)} \right)^{\log \log n}
\leq 4 \left( \frac{f(n)}{g(n)} \right)^{\log \log n},
\]

where

\[
f(n)^{\log \log n} = \exp\left( \frac{c \log n}{4(v + 1)(\log \log n)} - 1 \right)^{\log \log n}
\leq \exp\left( \frac{c \log n}{4(v + 1)} - 1 \right)
= n^{o(1)}
\]

and

\[
g(n)^{\log \log n} = \left( \frac{c \log n}{4(v + 1)(\log \log n)} \right)^{c \log n/4(v + 1)(\log \log n)}^{\log \log n}
= \left( \frac{c \log n}{4(v + 1)(\log \log n)} \right)^{c \log n/4(v + 1)}^{\log \log n}
= \Omega(n^{c/4-\varepsilon})
\]

for any \( \varepsilon > 0 \). Putting this all together, we obtain

\[
\Pr[N' > k \mid N \leq 2d \log n] \leq \frac{n^{o(1)}}{\Omega(n^{c/4-\varepsilon})} = O(n^{-c/4+\varepsilon}).
\]

Unconditioning, we obtain

\[
\Pr[N' > k] = O(n^{-c/4+\varepsilon} + n^{d(1-\log 4)}).
\]
Let $G'$ be the subgraph of $G$ consisting only of edges of length at most $\ell$, and let $D'$ denote the maximum degree of a vertex in $G'$. Repeating the above argument $4n$ times and using the union bound gives

$$\Pr\{D' > 4k\} = O(n^{1-c/4+\epsilon} + n^{1+d(1-\log 4)}).$$

Finally, all that remains is to argue that $G$ has no edges of length greater than $\ell$. An edge of length at least $\ell$ defines an empty region of area at least $\pi \ell^2/4$. For $\ell < \frac{1}{2}$, a portion of this empty region whose area is at least $(\ell/2)^2$ is contained in $D^2$ (see Figure 10). Therefore, the probability of there being any edge of length greater than $\ell = \sqrt{d \log n/n}$ is at most

$$4n(1-\ell^2/4)^{n-2} = 4n \left(1 - \frac{d \log n}{4n}\right)^{n-2} \leq 4ne^{-\frac{(n-1)d \log n}{4n}} \leq 4n^{1-(n-1)d/4n} = 4n^{1-(1-1/n)d/4}.$$

At last, let $D$ be the maximum degree of any vertex in $G$. Putting everything together, we obtain

$$\Pr\{D > 4k\} = O(n^{1-c/4+\epsilon} + n^{1+d(1-\log 4)} + n^{1-(1-1/n)d/4}) \to 0$$

for any $c > 4$ and $d > \max\{1/(\log 4 - 1), 4\}.$

3.3. Remarks

Why $D^2$? The proof of Theorem 3.2 actually shows that the probability that $G$ has a vertex of degree more than $c \log n \log \log n$ is $n^{-\Theta(c)}$. The last step in the proof requires that any edge of length $\ell$ defines a portion of the support set of area $\Omega(\ell^2)$ that is empty of points. This is true when the support set is $D^2$, but not true when the support set is the unit square $[0, 1]^2$. Indeed, the proof breaks down for points drawn from the unit square since, with probability $1/n$, some element, say $X_1$, simultaneously has the minimum $x$ and $y$ coordinates. In this case, the expected degree of $X_1$ is equal to the expected number of minimal elements among $X_1, \ldots, X_n$, which is, by Lemma 3.2, $\Theta(\log n)$.

In a situation where points are uniformly distributed in the unit square, the upper bound in Theorem 3.2 holds if we consider only the points whose distance from the boundary of the square is at least $\sqrt{d \log n/n}$. 

\begin{figure}[h]
\centering
\includegraphics[width=0.3\textwidth]{figure10.png}
\caption{An edge of length $\ell$ defines an empty subset of $D^2$ whose area is at least $(\ell/2)^2$.}
\end{figure}
Theorem 3.1 and Theorem 3.2 still hold. The arguments are almost identical with the exception that the definitions of a staircase and of minima and maxima are modified to take the value of $\theta$ into account. Although the value of $\theta$ appears in the intermediate calculations, for any constant $\theta$, the constants $c_1 = \frac{1}{4}$ and $c_2 = 4$ in Theorem 3.1 and Theorem 3.2 are unchanged (though the constant $4c$ in Theorem 3.2 becomes $2\pi/\theta c$). However, as noted above, to prove a version of Theorem 3.2, the support set must be rotated so that the difference in angle between any side of the upper bound in Theorem 3.2 becomes $2\pi/\theta$ is lower bounded by a constant.

Higher dimensions. Yao graphs are also defined for point sets in $\mathbb{R}^d$. The lower bound of Theorem 3.1 can be extended to show that Yao graphs of $n$ points uniformly and independently distributed in $[0, 1]^d$ have maximum degree $\Omega(\log n / \log \log n)$. Unfortunately, the proof of the upper bound in Theorem 3.2 does not continue to hold in $\mathbb{R}^d$.
