Endovascular Therapy of Hypoglossal Canal AVFs Presenting with Orbital Symptoms

Vladislav Miropolsky, Leodante B. da Costa, Thomas R. Marotta, Julian Spears

ABSTRACT: Objective: Dural arteriovenous fistulae (DAVF) of the hypoglossal canal region are rare lesions. We describe three cases of DAVF of the hypoglossal canal presenting with ocular symptoms and discuss the endovascular management options. Methods: Three consecutive patients with DAVF of the hypoglossal canal region presented with proptosis, chemosis and disturbances of extra-ocular mobility. Each patient was treated using a different endovascular approach, based on variations of the vascular access. Results: The cases and treatments are reviewed, with a literature review on the subject. Endovascular treatment, transvenous or trans-arterial was curative in all cases. Conclusion: DAVF of the hypoglossal canal region can present with ocular manifestations very similar to DAVF of the cavernous sinus or carotid-cavernous fistulas. Endovascular treatment is usually feasible and effective, but an understanding of the vascular anatomy and pathophysiology of the disease are of utmost importance when planning the approach.

Dural arteriovenous fistulae (DAVF) are abnormal arteriovenous shunts that occur in the dura. Clinical manifestation is related to the pattern of venous drainage and can include ocular symptoms, bruit, congestive venous encephalopathy and intracranial hemorrhage. Approximately 50% of dural arteriovenous fistulae occur in the posterior fossa, and typically involve the transverse and sigmoid sinuses. Involvement of the tentorial or marginal sinus is less common. Borden et al have classified cranial DAVF as follows: Type I DAVFs are those that drain directly into the dural venous sinus or meningeal vein. Type II DAVFs are those that drain into the venous sinus with retrograde drainage into subarachnoid (superficial) veins. Type III DAVFs are those that drain into the subarachnoid veins. Type I DAVFs usually present with minor symptoms. In contrast, Types II and III DAVFs cause serious problems and require treatment.¹
Dural arteriovenous fistulae located in the hypoglossal canal region have been described but are extremely rare. Patients may present with cranial nerve neuropathy or symptoms related to increased intracranial or intraocular venous pressure. The relative distance and apparent disconnection between the eyes and the hypoglossal canal may be misleading when investigating patients with ocular symptoms secondary to increased intraocular venous pressure. The treatment of these lesions can be challenging due to the complex anatomy with highly varied arterial supply and venous drainage patterns.

We present three cases of dural arteriovenous fistulae located in the hypoglossal canal region, all presenting with orbital symptoms. Each of those lesions was managed with a different endovascular approach, and a discussion of the treatment options is provided.
**Clinical Cases**

**Case 1: Superficial Venous Approach (Superior Ophthalmic Vein)**

A 50-year-old male with a history of a long-standing audible bruit on the right presented with an abrupt onset of right eye chemosis, proptosis and glaucoma. Physical examination revealed right 6th nerve palsy and a chemotic, proptotic eye with increased intraocular pressure. Visual acuity was stable. Magnetic resonance imaging of the brain revealed edema and diffuse thickening of extra-ocular eye muscles and a dilated right superior ophthalmic vein. A CT venogram showed no connection between the right internal jugular vein and ipsilateral inferior petrosal sinus (IPS). The IPS communicated, however, with an intraosseous venous channel traversing the right hypoglossal canal. Digital subtraction angiography showed a dural AVF of the right hypoglossal canal supplied by the neuromeningeal branch of the right ascending pharyngeal artery and multiple small arteries originating from the occipital artery. Retrograde venous drainage of the fistula occurred through the IPS to the cavernous sinus and through the superior ophthalmic vein and facial vein with cortical venous reflux. A superior ophthalmic vein approach was selected after an unsuccessful attempt of an approach through the right internal jugular vein. The right superior ophthalmic vein was dissected and cannulated using a direct surgical cut-down. A total of six fibered GDC platinum coils (Boston Scientific Target) were placed in the fistulous pouch of the right hypoglossal canal with complete occlusion of the fistula and immediate improvement in the patient’s symptoms (Figure 1).

**Case 2: Jugular Venous Approach (Jugular Vein)**

A 74-year-old male presented with an eight-month history of persistent right eye chemosis. Cerebral angiography showed a DAVF of the right hypoglossal canal region supplied

---

**Figure 2:** (A) Arterial injection demonstrates a DAVF in the hypoglossal canal with main arterial supply from right ascending pharyngeal artery and stylomastoid branch of the occipital artery. Venous drainage is up through IPS (arrow) and through the cavernous sinus (arrowhead) into the orbital venous system. (B) Jugular venous access for deposition of multiple coils from mid portion of the IPS towards the venous pouch within the hypoglossal canal. (C) Post procedural angiogram demonstrates coils filling the venous pouch. The superior ophthalmic vein retrograde drainage has now been excluded.
predominantly by the neuromeningeal branch of the right ascending pharyngeal artery and a stylomastoid branch of the occipital artery. Venous drainage of the fistula was in both an anterograde direction through the jugular bulb and jugular vein as well as in a retrograde direction via the IPS, cavernous sinus and superior ophthalmic vein. Superselective angiography was performed and through a transvenous approach via the right jugular vein, seventeen bare and fibered coils were placed into the mid-portion of the IPS coiling in a caudal direction towards the venous pouch located in the hypoglossal canal region, disconnecting completely the retrograde drainage towards the eye. The patient’s symptoms improved immediately with complete resolution at follow up in six weeks (Figure 2).

Case 3: Transarterial Approach

A 50-year-old female presented with right chemosis, diplopia and headache. Computed tomography suggested the presence of a fistula and a cerebral angiogram confirmed a Borden type III DAVF involving the region of the hypoglossal canal supplied by multiple branches of bilateral external carotid arteries and vertebral arteries, and the cavernous segment of the right internal carotid artery. Venous drainage was primarily via the right IPS, with reflux into right sphenoparietal sinus, right superior ophthalmic vein and cortical veins. A venous approach through both internal jugular veins and the left IPS (an attempt to cross transclival or transsellar venous anastomoses into the right IPS) was unsuccessful. Transarterial embolization initially with polyvinyl alcohol to reduce flow through the left stylomastoid and left ascending pharyngeal arteries and eventually with n-butyl-cyanoacrylate using superselective catheterization of right ascending pharyngeal artery was done. Venous penetration of embolic material into the right IPS and right cavernous sinus was noted on the final angiogram on the day of treatment and a follow-up cerebral angiogram two weeks later confirmed complete occlusion of the DAVF. The patient’s symptoms resolved completely (Figure 3).

DISCUSSION

Dural arteriovenous fistulae are uncommon lesions. Clinical presentation can vary widely according to the pattern of venous drainage, ranging from benign symptoms that include bruit or orbital/ocular symptoms to more ominous presentation and natural history, with a high rate of intracranial hemorrhage, when cortical venous reflux is present.2,3 Although the pathogenesis of DAVFs is not yet well understood, they are considered acquired lesions, and local angiogenic factors, hypoxia and trauma may play an important role in their development.5–13 Despite the fact that approximately 50% of the lesions are located in the posterior fossa, involvement of the hypoglossal canal region is extremely rare.

Normal MR imaging appearance of the hypoglossal canal includes variable size of the canal that contains a combination of venous enhancement and occasional linear non-enhancement of the hypoglossal nerve rootlets. Intracranial extension of enhancement beyond the confines of the bony canal is also recognized. Stuckey has described a case of marked asymmetric protrusion of the hypoglossal canal emissary veins into the cerebellomedullary cisterns with potential to mimic diseases such as a nerve sheath tumor. Caution should be exercised when interpreting an enhancing structure protruding form a skull base foramen by first correlating with lack of patient symptomatology and considering a nearby DAVF or impaired internal jugular venous return with prominent veins as potential differential diagnostic possibilities. To aid in correct diagnosis, alternative imaging planes and flow-sensitive sequences can be used.14

Chemosis and proptosis are symptoms usually associated with retrograde venous drainage from arteriovenous fistulas in the region of the cavernous sinus (either DAVF or carotid-cavernous fistula (CCF)). In addition, it has been reported that clinical symptoms associated with marginal sinuses arteriovenous
fistulas can mimic those of CCF.\textsuperscript{15} Although rare, dural fistulae in the region of the hypoglossal canal can present with ocular symptoms very similar to arteriovenous fistulae of the cavernous sinus region, and probably should be included in the differential diagnosis. Despite the limited number of cases available in the literature ocular symptoms appear to be a relatively common clinical expression of these lesions.\textsuperscript{16-18} Venous and arterial anatomy of the region of the hypoglossal canal and its connections with ocular vessels is complex and a clear understanding is essential before treatment can be planned. The vascular supply to the dura in the hypoglossal canal region includes distal branches of the ascending pharyngeal (AP) and occipital arteries. The AP artery consists of two major trunks, the pharyngeal trunk and the neurovascular trunk. From the neurovascular trunk arises the hypoglossal branch, jugular branch, internal auditory branch and clival branches, the most important being the former two. The hypoglossal branch traverses the hypoglossal canal to supply the posterior fossa meninges and the vasa nervorum of cranial nerve XII with a posterior descending branch contributing to the odontoid arch system. The jugular branch extends to the posterior fossa to the jugular foramen and supplies the vasa nervorum of cranial nerves IX, X and XI. Several small branches leave the jugular foramen to supply the meninges of the internal auditory canal, the dura of the IPS and possibly the vasa nervorum of cranial nerve VI. The occipital artery is a branch of the external carotid artery and infrequently from the internal carotid artery. It courses obliquely posteriorly to the medial surface of the mastoid process. As it penetrates the skull though the emissary foramen it bifurcates into one branch that courses antero-laterally and joins the meningeal branches of the ascending pharyngeal artery and another branch that courses postero-superiorly to join the branches of the posterior meningeal artery. The venous plexus within the hypoglossal canal is referred to as the anterior condylar vein. It originates at the junction of the jugular bulb and IPS and transverses the hypoglossal canal to join the IPS. The venous network at the skull base is complex, including the marginal sinus, posterior condylar emissary vein, and the vertebral and basilar venous plexuses. This network provides the anatomical basis for the communication with the cavernous sinus and orbital veins if retrograde flow caused by a fistula is present.\textsuperscript{18-21}

Symptoms of cranial DAVFs are a consequence of the pattern of venous drainage. Fistulae with cortical venous reflux, more common in the tentorium and transverse-sigmoid sinus, have a high risk of hemorrhage, while ocular symptoms such as proptosis, chemosis, diplopia and increased intraocular pressure are usually seen in DAVFs of the region of the cavernous sinus.\textsuperscript{14,22} One would expect that lesions located in the occipital bone, including the hypoglossal canal region, present themselves with symptoms such as bruit or, in the case of cortical venous reflux, hemorrhage. As our series and a review of the available literature of these rare lesions demonstrate,\textsuperscript{16,17} DAVF of the hypoglossal canal should be included in the differential diagnosis of ocular symptoms, despite the considerable distance between the hypoglossal canal and the orbital veins. As is the case with CCF, meticulous ophthalmologic care must be provided with serial visual acuity and intraocular pressure measurements. Any change, including improvement in the ophthalmologic symptoms, may signify changes in the fistula and requires prompt investigation. Considering the complexity of open surgical approaches to the region, with potential morbidity and significant blood loss,\textsuperscript{19,21,23} treatment should always include careful evaluation of endovascular options. Different endovascular approaches are described and treatment should be tailored to specific characteristics of each case, since size and accessibility of vascular supply and drainage may vary from case to case. Digital subtraction angiography (DSA) is a standard examination for diagnosing the DAVF and detailed examination of its arterial supply and venous drainage pathways. The location and intraosseous extent of the lesion can be effectively studied using computed tomography and magnetic resonance angiography. Endovascular treatment options include: transvenous embolization from ipsilateral jugular vein or from the contralateral jugular vein across the IPS to the ipsilateral fistula, embolization via superior ophthalmic vein to hypoglossal canal region and multiple selective trans-arterial embolizations. Understanding of the complex venous anatomy at the skull base and its possible connections is essential in planning the endovascular approach. Trans-arterial embolization with liquid embolic agents, n-butyl-cyanoacrylate (NBCA) or OnyxR (EV3), is known to carry significant risk including lower cranial nerve palsies and neurointerventionalists must have a comprehensive understanding of the local anatomy and associated anastomoses to minimize these risks. A complete angiographic study, including a careful evaluation of the brain venous drainage, is mandatory. When feasible, a transvenous approach through the jugular vein is the preferred treatment as access is relatively simple and transvenous embolization has a higher likelihood of achieving complete occlusion than transarterial embolization. When access from the jugular system is not feasible, either from the ipsilateral side or from the contralateral side across the IPS, a transvenous approach through a superior ophthalmic vein cut-down, as described for CCF, can be effective. While transvenous embolization is preferable, transarterial embolization can also be effective in selected cases, either as a curative treatment or in order to reduce flow through the fistula, palliating symptoms or as an adjuvant to other approaches. Superselective injection of embolic material in the occipital and ascending pharyngeal artery should be performed bearing in mind that connections with the vertebral artery are common.

Dural fistulae located in the hypoglossal canal region are rare. Despite the relative distance and apparent disconnection between the eyes and the hypoglossal canal, ocular symptoms are the presenting symptom in a significant percentage of patients who may present with cranial nerve neuropathy and/or symptoms of increased intraocular venous pressure. The treatment of these lesions can be challenging. Endovascular treatment is a very attractive option and should be carefully planned, taking into account arterial supply and venous drainage with particular attention to the complex anatomy with variable arterial supply and venous drainage patterns. Each patient in our series was managed using a different endovascular approach highlighting the heterogeneous nature of these rare lesions.
