In the present review concerning stroke, we evaluate the roles of B vitamins, homocysteine and antioxidant vitamins. Stroke is a leading cause of death in developed countries. However, current therapeutic strategies for stroke have been largely unsuccessful. Several studies have reported important benefits on reducing the risk of stroke and improving the post-stroke-associated functional declines in patients who ate foods rich in micronutrients, including B vitamins and antioxidant vitamins E and C. Folic acid, vitamin B6 and vitamin B12 are all cofactors in homocysteine metabolism. Growing interest has been paid to hyperhomocysteinaemia as a risk factor for CVD. Hyperhomocysteinaemia has been linked to inadequate intake of vitamins, particularly to B-group vitamins and therefore may be amenable to nutritional intervention. Hence, poor dietary intake of folate, vitamin B6 and vitamin B12 are associated with increased risk of stroke. Elevated consumption of fruits and vegetables appears to protect against stroke. Antioxidant nutrients have important roles in cell function and have been implicated in processes associated with ageing, including vascular, inflammatory and neurological damage. Plasma vitamin E and C concentrations may serve as a biological marker of lifestyle or other factors associated with reduced stroke risk and may be useful in identifying those at high risk of stroke. After reviewing the observational and intervention studies, there is an incomplete understanding of mechanisms and some conflicting findings; therefore the available evidence is insufficient to recommend the routine use of B vitamins, vitamin E and vitamin C for the prevention of stroke. A better understanding of mechanisms, along with well-designed controlled clinical trials will allow further progress in this area.

B vitamins: Homocysteine: Antioxidant vitamins E and C: Oxidative stress: Stroke

Introduction

Stroke is a leading cause of death in developed countries. However, current therapeutic strategies for stroke have been largely unsuccessful. It is estimated that stroke is responsible for 9-5% of all deaths and 5-1 million of the 16-7 million CVD deaths1. Furthermore, nearly one-third of stroke survivors have some degree of dementia after stroke. Of patients who had ischaemic stroke, 32% had dementia based on comprehensive neurological and psychological testing, clinical mental status interviews, MRI scans and detailed histories collected3-4. Importantly, dementia is more common in stroke patients who are older, smoke and have lower levels of education3. In addition, vascular dementia often coexists with Alzheimer’s disease, and the presence of Alzheimer’s disease may predispose one to the development of vascular dementia. In fact, the 5% prevalence in cognitive impairment that occurs in the elderly over the age of 65 years increases sharply after ischaemic stroke, up to 38%. Cognitive impairment is associated with death or disability at 4 years after a stroke5. But vascular dementia, which is the second most important cause of cognitive impairment and dementia associated with ageing in the USA, is the most preventable form affecting the elderly.

The realisation that brain ischaemia elicits more robust brain damage when nutritional status is poorer provides a fertile ground for the discovery of novel therapeutic agents and nutritional intervention for stroke. Deficiency of B vitamins and antioxidant vitamins E and/or C appears to increase cognitive impairment in stroke patients6-8. Better understanding of the role that specific nutrients play on vasculature and brain’s cell response in stroke patients may

Abbreviations: Hcy, homocysteine; MCP-1, monocyte chemoattractant protein-1.
be relevant to reduce the incidence of cognitive impairment and dementia associated with stroke. Interestingly, B vitamins play critical roles in cell function\(^{(9)}\). For example, folate in the 5-methyltetrahydrofolate form is a co-substrate required by methionine synthase to convert homocysteine (Hcy) to methionine; consequently, Hcy accumulates when folate is low\(^{(10,11)}\). High Hcy is strongly associated with atherosclerotic vascular disease and stroke\(^{(12)}\). Furthermore, several surveys have shown positive correlation between low folate levels and dementia\(^{(13)}\). B\(_{12}\) is important in maintaining the nervous system where it plays a vital role in the metabolism of fatty acids essential to maintain myelin\(^{(14)}\). Vitamin B\(_{12}\) is also required for methionine synthesis from Hcy\(^{(15)}\). Prolonged B\(_{12}\) deficiency can lead to nerve degeneration and irreversible neurological damage\(^{(16)}\). Vitamin B\(_{6}\) is needed for the synthesis of neurotransmitters such as serotonin and dopamine. A deficiency of vitamin B\(_{6}\) may also contribute to increase levels of Hcy. Fig. 1 shows the biochemical pathways of Hcy metabolism with the roles of folate, B\(_{6}\), and B\(_{12}\)\(^{(15)}\).

Several reports have suggested a relevant effect of dietary antioxidants, including vitamins E and C, on stroke prevention\(^{(17} – 19\))\). Ascorbic acid administration to a primate model after focal cerebral ischaemia significantly reduced the size of the infarct\(^{(20)}\). Furthermore, data from the Third National Health and Nutrition Examination Survey (NHANES III) indicate a biological interaction between ascorbic acid and alcohol and suggest that higher intake of ascorbic acid may be associated with a decreased vascular risk among drinkers\(^{(21)}\). Among 87 245 US female registered nurses, aged 34–59 years, higher antioxidant vitamin consumption was associated with a reduced risk of ischaemic stroke\(^{(19)}\). In addition, high consumption of cruciferous vegetables and citrus fruit juice reduced the risk of stroke\(^{(22)}\). From a 25-year follow-up study of middle-aged men who participated in the Framingham Cardiovascular Study\(^{(23)}\), investigators re-examined 832 men, aged 45–65 years, who had been free of CVD when they began the Framingham Study in 1969 and observed an inverse association between fruit and vegetable intake and the development of stroke.

A study of the intake of antioxidants and the risk of stroke provides tantalising, albeit preliminary, evidence that vitamin E might be of value in reducing the risk of stroke\(^{(24)}\). An inverse association was seen between death from stroke and vitamin E intake from food, which reflected a continued association from the lowest to the highest intake categories, thus supporting a protective role for vitamin E.

**Fig. 1.** Pathways for the metabolism of homocysteine. Normal trans-sulfuration requires cystathionine β synthase with vitamin B\(_{6}\) as cofactor. Remethylation requires 5,10-methylenetetrahydrofolate reductase (5,10-MTHFR) and methionine synthase. The latter requires folate as co-substrate and vitamin B\(_{12}\) (cobalamin) as cofactor. An alternative remethylation pathway also exists using the cobalamin-independent betaine--homocysteine methyltransferase\(^{(10)}\). DMG, dimethylglycine.
or other antioxidant vitamins\(^{24}\). Previous studies reported a significant reduction in the incidence of ischaemic events in patients taking vitamin E plus aspirin compared with patients taking only aspirin\(^{26-27}\). Vitamin C status may be a determinant of cognitive function in elderly people through its effect on atherosogenesis. Low consumption of vitamin C as well as low plasma levels were associated with a greater risk of cognitive disorders in a 20-year follow-up study\(^{66}\).

As the number of older people grows rapidly worldwide, along with the fact that elderly people are also living longer, the risk of stroke and stroke-associated dementia – which is one of the most common causes of cognitive impairment – is increasingly becoming an important public health problem. Since nutrition plays a role in the ageing process, relatively simple and inexpensive treatments involving dietary intervention and vitamin supplementation may reduce the risk of stroke and ameliorate the neurological and neurocognitive impairments associated with stroke. Therefore, in the present review we will examine the potential role that nutritional status – specifically B vitamins and antioxidants – plays in reducing the deleterious effects associated with stroke. Tables 1 and 2 show a summary of some of the observational and intervention studies in the literature regarding B vitamins, Hcy and stroke, and antioxidant vitamins E and C and stroke, respectively.

### Nutrition and stroke

The dietary guidelines of the American Heart Association include specific recommendations tailored to an individual’s risk of heart disease and stroke that are based on an analysis of hundreds of studies\(^{28}\). This recommended diet provides a generous amount of micronutrients essential for good health; however, a very small percentage of the population follows it. In spite of these recommendations, several studies have indicated that few of us eat well, and nutritional deficiencies or low nutrient levels in tissues are very common. For example, in a study of 402 elderly Europeans living at home, the nutrient content of their diet was found to be low: folate intake was low in 100 % of those studied, Zn in 87 %, vitamin B\(_6\) in 83 % and vitamin D in 62 %\(^{29}\).

A cross-sectional study looking into the association of dietary \(\beta\)-carotene, vitamin C and vitamin E with peripheral arterial disease was performed in Rotterdam, the Netherlands, between 1990 and 1993 in 4367 subjects aged 55–94 years. Diet was assessed with a FFQ. In multivariate-adjusted logistic regression analyses, vitamin C and E intake was significantly inversely associated with peripheral arterial disease\(^{30}\).

Brussaard \textit{et al.} \(^{31}\) assessed the adequacy of folate intake and status among adults in the Netherlands. They concluded that the folate intake among adult men and women was adequate in view of recommended daily intakes. However, the folate intake among women did not meet the recommendation for those who want to become pregnant. According to criteria derived from Hcy metabolism as related to CVD, folate status may not be adequate in 60–79 % of adult age–sex groups. However, the percentage of adults with low folate status is going to vary widely between countries dependent on folic acid fortification and other dietary considerations.

Folate, riboflavin, vitamin B\(_6\) and vitamin B\(_{12}\) are essential in Hcy metabolism, and elevated plasma Hcy concentration is associated with an increased risk of CVD. In a random sample of 2435 men and women, aged 20–65 years, who were examined between 1993 and 1996, B vitamins were inversely related to the plasma Hcy concentration; however, only folate intake remained inversely associated with the plasma Hcy concentration following multivariate-adjusted logistic regression analyses\(^{32}\). Data consistently indicate that folic acid supplementation in the form of vitamin tablets is the most effective strategy to lower mild-to-moderately elevated Hcy\(^{33}\). However, in folic acid-fortified populations, vitamin B\(_{12}\) status emerges as the most important nutritionally modifiable determinant of Hcy levels\(^{34,35}\). Steps to either reduce the prevalence of vitamin B\(_{12}\) deficiency or to identify and treat individuals with vitamin B\(_{12}\) deficiency could further reduce the prevalence of hyperhomocysteaemia\(^{35}\).

To assess how changes in Hcy levels may influence post-stroke response, Howard \textit{et al.} \(^{36}\) used a multicentre design study to examine changes on Hcy during the 2 weeks after an incident stroke. They collected blood samples from fifty-one subjects at days 1, 3, 5, 7, and between 10 and 14 d after the stroke. The estimated mean Hcy level at baseline was 11·3 (SEM 0·5) \(\mu\text{mol/l, which increased consistently to 12·0 (SEM 0·5), 12·4 (SEM 0·5), 13·3 (SEM 0·5) and 13·7 (SEM 0·7) \(\mu\text{mol/l at days 3, 5, 7 and 10–14, respectively. The magnitude of the changes in Hcy was not affected by age, smoking status, alcohol use, history of hypertension or diabetes, or Rankin scale score. This study would be strengthened by an assessment of Hcy taken during the convalescent period. With this additional assessment, the authors would have been able to assess the proportion of the change between the acute and convalescent period. These observations suggest that the relevance and clinical interpretation of Hcy after stroke require an adjustment in time. Much of the evidence of the association of Hcy and stroke risk is based on a comparison of Hcy levels after stroke with Hcy levels of controls. The results by Howard \textit{et al.} \(^{36}\) suggested that Hcy levels would be increased in blood collected later after the stroke. Therefore, the interpretation that a high Hcy level is a risk factor for stroke may be misleading; rather, it could be that the elevated Hcy is a consequence rather than a cause of the stroke.

Mezzano \textit{et al.} \(^{37}\) investigated the relative contributions of inflammation and high Hcy to abnormal oxidative stress, endothelial activation/dysfunction and haemostatic activation in patients with chronic renal failure, and concluded that inflammation, endothelial cell dysfunction and haemostatic activation emerge as a major cardiovascular risk in chronic renal failure.

Observational studies support the importance of modifying lifestyle-related risk factors such as diet, physical activity and alcohol use in stroke prevention. Moderately elevated Hcy levels may be associated with stroke and are associated with deficiency of dietary intake of folate, vitamin B\(_6\) and vitamin B\(_{12}\). Consumption of a diet rich in fruits, vegetables, folate, K, Ca, Mg, dietary fibre, fish and...

Launer & Kalmijn (1998) Antioxidants and cognitive function Review

Vitamin E was not associated with any subtype of stroke. Dietary vitamin C was inversely associated with risk for intracerebral haemorrhage, whereas no association was found between intake of vitamin C and risks for cerebral infarction and subarachnoid haemorrhage.

Serum vitamin C concentration was inversely associated with incidence of stroke, both cerebral infarction and haemorrhagic stroke.

Intracranial and head trauma patients had significantly lower plasma levels of vitamin C compared with healthy subjects. Ascorbic acid was significantly inversely correlated with the severity of the neurological impairment and with the major diameter of the lesion.

Low plasma vitamin C was associated with an increased risk of stroke, especially among hypertensive and overweight men.

High dietary intake of antioxidants, in particular vitamin C and – in smokers – vitamin E, reduced the risk of stroke.

Plasma vitamin C concentrations may serve as a biological marker of lifestyle or other factors associated with reduced stroke risk and may be useful in identifying those at high risk of stroke.

Vitamin E administration in pharmacological doses improved the neurological condition in two patients and also corrected some of the patients’ erythrocyte cell abnormalities.

Vitamin E slowed the progression of AD.

Vitamin E supplementation showed a protective effect against ischaemic stroke.

Vitamin E supplementation appears to have a significant effect in preventing ischaemic stroke in high-risk hypertensive patients.

In patients with vascular disease or diabetes mellitus, long-term vitamin E supplementation does not prevent cancer or major cardiovascular events and may increase the risk for heart failure.

There were no overall effects of ascorbic acid, vitamin E or β-carotene on cardiovascular events among women at high risk for CVD.

Ascorbate and other antioxidant nutrients are presumed to play a pivotal role in minimising the damage from oxidative products.

Vitamin C’s protective effect against stroke is well documented whereas the evidence that vitamin C is protective against CHD is less consistent.

Effect of antioxidants on cognitive impairment or dementia needs further investigation.

CWE Study, The Chicago Western Electric Study; NHNE Survey, National Health Nutrition Examination Survey; AD, Alzheimer’s disease; PD, Parkinson’s disease; SOD, superoxide dismutase; NOMAS, The Northern Manhattan Stroke Study.

B vitamins, folate, vitamin B2 and vitamin B6, play an important role in cognitive functions in ageing. In humans, a number of epidemiological case–control and prospective studies have indicated that subclinical deficiencies of essential nutrients such as antioxidants (vitamins C and E), folic acid, vitamin B6 and -carotene, have been associated with higher risk of cognitive impairment (8). Current scientific evidence has also indicated that higher intake of whole grain foods was associated with a reduced risk of subclinical vitamin B12 deficiency (32,43,44). (About a fifth of patients with acute stroke are women who do not take aspirin regularly. Other authors have also reported that fish consumption is associated with a reduced risk of ischaemic stroke in women (53). Another hand, intake of monounsaturated fat has been associated with a reduced risk of ischaemic stroke in men (55). On the other hand, intake of polyunsaturated fats is associated with a reduced risk of ischaemic stroke (56).)

**Note:**
- Large randomised trials are now in progress to identify the best aspirin dose for stroke prevention in patients with a low serum albumin (57).
- There is also evidence that daily aspirin may protect against stroke (34,42).
- Milk may provide protective effect on stroke (22).
- There is also evidence that daily aspirin may protect against stroke (34,42).
accompany folate deficiency. Numerous animal studies have also shown that folate deficiency during pregnancy can impair proper development of fetal central nervous system structures. Folate deficiency in pregnant women is associated with an increased incidence of spina bifida and other neural defects\(^{(56)}\). Vitamin B\(_{12}\) deficiency in adults is usually not the result of reduced dietary intake but rather reflects reduced intestinal absorption of the vitamin. A number of disease conditions can alter production of the intrinsic factor that is essential for absorption of vitamin B\(_{12}\) from the intestine. Atrophic gastritis is an important cause of vitamin B\(_{12}\) malabsorption. This condition primarily affects the ability to extract vitamin B\(_{12}\) from foods. Deficiency of vitamin B\(_{12}\) impairs the ability of the bone marrow to produce erythrocytes and thus leads to anaemia, similar to what is observed with folate deficiency. Vitamin B\(_{12}\) deficiency can also result in irreversible damage to the nervous system causing swelling, demyelination and death of neurons.

Evidence of the importance of the B vitamins folic acid, vitamin B\(_{12}\) and vitamin B\(_{6}\) for the wellbeing and normal function of the brain derives from data showing neurological and psychological dysfunction in vitamin-deficiency states and in cases of congenital defects of one-carbon metabolism. A review by Selhub et al.\(^{(57)}\) indicated that the status of these vitamins is frequently inadequate in the elderly and recent studies have shown associations between loss of cognitive function or Alzheimer’s disease and inadequate B vitamin status. The authors suggest that low B vitamin intake may affect methylation reactions, which are crucial for normal brain function. Poor B vitamin status can also result in high Hcy, a risk factor for occlusive vascular disease, stroke and thrombosis and thus may contribute to brain ischaemia. Evidence of the importance of B vitamins (B\(_{12}\), B\(_{6}\) and folate) in neurocognitive and other neurological functions is derived from reported cases of severe vitamin deficiencies, particularly pernicious anaemia, or homozygous defects in genes that encode for enzymes of one-carbon metabolism\(^{(58)}\); however, the data from a recent systematic review of randomised trials do not yet provide adequate evidence of an effect of vitamin B\(_{6}\) or B\(_{12}\) or folic acid supplementation, alone or in combination, on cognitive function testing in individuals with either normal or impaired cognitive function\(^{(59)}\). Low levels of folate and vitamin B\(_{6}\) have been regarded to confer an increased risk of atherosclerosis\(^{(60)}\). High plasma Hcy concentration is a risk factor for atherosclerosis, and circulating concentrations of Hcy are related to vitamin B\(_{12}\) status, as well as folate and vitamin B\(_{6}\). If elevated Hcy promotes cognitive dysfunction, then lowering Hcy by means of B vitamin supplementation may protect cognitive function by arresting or slowing the disease process\(^{(61)}\). Although elevated plasma Hcy concentrations have been implicated in the risk of cognitive impairment and dementia, it is unclear whether low vitamin B\(_{12}\) or folate status is responsible for cognitive decline\(^{(62)}\).

Various studies have suggested that a generous intake of folate and B vitamins may be beneficial in stroke prevention by reducing the level of plasma Hcy\(^{(60)}\). The association between dietary intake of folate and the subsequent risk of stroke and CVD is well documented. Participants in the National Health and Nutrition Examination Survey I (NHANES I) included 9764 US men and women aged 25–74 years who were free of CVD at baseline. The results showed that the relative risk of incidence of stroke events was lower among subjects with dietary folate intake in the highest quartile (405.0\(\mu g/d\)) compared with those in the lowest quartile (99.0\(\mu g/d\)), after adjustment for established cardiovascular risk factors and dietary factors\(^{(63)}\). A recent study evaluated whether a combination of folic acid, vitamin B\(_{6}\) and vitamin B\(_{12}\) lowers the risk of CVD among high-risk women with and without CVD. A total of 5442 women who were US health professionals aged 42 years or older, with either a history of CVD or three or more coronary risk factors, were enrolled in a randomised, double-blind, placebo-controlled trial to receive a combination pill containing 2.5 mg folic acid, 50 mg vitamin B\(_{6}\) and 1 mg vitamin B\(_{12}\). They were treated for 7.3 years from April 1998 until July 2005. After 7.3 years of treatment and follow-up, the combination of B vitamins tested did not reduce a combined end point of total cardiovascular events among high-risk women, despite significant Hcy lowering\(^{(64)}\). In addition, the results of the Heart Outcomes Prevention Evaluation (HOPE-2) study, showed that combined daily administration of 2.5 mg folic acid, 50 mg vitamin B\(_{6}\) and 1 mg vitamin B\(_{12}\) for 5 years had no beneficial effects on major vascular events in a high-risk vascular disease population\(^{(65)}\), although fewest patients assigned to active treatment than to placebo had a stroke (relative risk 0.75; 95% CI 0.59, 0.97). As well, Bønaa et al.\(^{(66)}\) evaluated the efficacy of Hcy-lowering treatment with B vitamins for secondary prevention in patients who had had an acute myocardial infarction. The trial included 3749 men and women who had had an acute myocardial infarction within 7 d before randomisation. Patients were randomly assigned, in a 2 \(\times\) 2 factorial design, to receive one of the following four daily treatments: 0.8 mg folic acid, 0.4 mg vitamin B\(_{12}\) and 40 mg vitamin B\(_{6}\); 0.8 mg folic acid and 0.4 mg vitamin B\(_{12}\); 40 mg vitamin B\(_{6}\); or placebo. The primary end point during a median follow-up of 40 months was a composite of recurrent myocardial infarction, stroke and sudden death attributed to coronary artery disease. The authors conclude that treatment with B vitamins did not lower the risk of recurrent CVD after acute myocardial infarction.

The folic acid fortification programme in the USA has decreased the prevalence of low levels of folate and hyperhomocysteinaemia to 1% or lower\(^{(35)}\). Folate is distributed widely in green leafy vegetables, citrus fruits and animal products. The biologically active form of folic acid is tetrahydrofolic acid, which plays a key role in the transfer of one-carbon units, such as methyl, methylene and formyl groups, to the essential substrates involved in the synthesis of DNA, RNA and proteins. More specifically, tetrahydrofolic acid is involved in the enzymatic reactions necessary for the synthesis of purine, thymidine and amino acids. Manifestations of folate deficiency, thereafter, not surprisingly, would result in impairment of cell division, accumulation of possibly toxic metabolites such as Hcy, and impairment of methylation reactions involved in the regulation of gene expression. Mechanistically speaking, current theory proposes that folate is essential for the
synthesis of S-adenosylmethionine, which is involved in numerous methylation reactions. This methylation process is central to the biochemical basis of proper neuropsychiatric functioning.

A large body of evidence suggests that intake of folate and B vitamins may be beneficial in stroke prevention by reducing levels of plasma Hcy; however, limited information is available regarding dietary intake of vitamins or use of vitamin supplements by stroke patients. Beamer et al. (67) collected information regarding the use of vitamin supplements from 231 patients with acute ischaemic stroke. These authors also recorded vitamin intake from ninety-four subjects with similar clinical risk factors for stroke, including hypertension, diabetes, myocardial ischaemia, and fifty-nine healthy community volunteers who denied the presence of stroke risk factors and who were matched in age with the two vascular groups. Fewer subjects who had stroke were taking vitamins, compared with healthy elderly community volunteers. In addition, Hcy levels available from forty-nine stroke patients, thirty-one patients with stroke risk factors and seven control subjects were significantly lower in subjects taking vitamins. The pattern of lower Hcy values with vitamin use was consistent across groups, including stroke patients (13·9 (SD 6·7) μmol/l) v. 14·6 (SD 4·1) μmol/l), at-risk elderly subjects (13·5 (SD 4·3) μmol/l) v. 15·0 (SD 6·9) μmol/l) and healthy elderly subjects (7·1 (SD 0·1) μmol/l) v. 10·5 (SD 2·3) μmol/l). It was concluded that Hcy levels are influenced by a complex interaction of sex, dietary levels of protein intake, dietary and/or supplemental vitamin use and cardiovascular risk factors. These results suggest that the use of vitamin supplements may be associated with lower levels of Hcy in elderly individuals whether or not stroke or stroke-related risk factors are present. Also, these data suggest that less frequent use of vitamin supplementation in the elderly may be associated with an increased risk for stroke (67). Different epidemiological studies suggest that raised plasma concentrations of total Hcy may be a common, causal and treatable risk factor for atherothromboembolic ischaemic stroke. Therefore, a study aimed to assess the effect of Vitamins to Prevent Stroke (VITATOPS) – an international, multi-centre, randomised, double-blind, placebo-controlled clinical trial – using a multivitamin therapy (folic acid 2 mg, vitamin B₁₂ 500 μg) is currently going on. It is planned that 8000 patients will be randomised and followed up for a mean period of 2.5 years (range 1–8 years) by the end of 2009. This study is expected to generate relevant data on the potential role of these nutrients on stroke and other atherothromboembolic vascular events in patients with recent stroke or transient ischaemic attacks. Publication of the results of the landmark Vitamin Intervention for Stroke Prevention (VISP) Trial is the first evidence from a large randomised controlled trial of the effect of lowering total Hcy via folic acid-based multiple B vitamin supplementation on the incidence of ‘hard’ clinical events, such as recurrent stroke, in patients with recent ischaemic stroke (69,70). Hankey & Eikelboom (71) believe that the Hcy hypothesis of atherothrombotic vascular disease in general, and stroke in particular, remains viable. Two studies using different methods have yielded consistent results in support of the hypothesis (72,73).

Several studies are in progress to determine whether treatment with folic acid in combination with vitamins B₉ and B₁₂ will reduce the risk of stroke in patients with increased serum Hcy. A meta-analysis of twelve randomised trials of vitamin supplements to lower Hcy levels was carried out to determine the optimal dose of folic acid required to lower Hcy levels and to assess whether vitamin B₁₂ or vitamin B₉ had additive effects (74). This meta-analysis demonstrated that reductions in blood Hcy levels were greater at higher pre-treatment blood Hcy levels and at lower pre-treatment folate concentrations. After standardisation for a pre-treatment Hcy concentration of 12 μmol/l and folate concentration of 12 mmol/l (approximate average concentrations for Western populations), dietary folate acid reduced Hcy levels by 25 (95 % CI 23, 28) %, with similar effects in a daily dosage ranging from 0·5 to 5 mg. Vitamin B₁₂ (mean 0·5 mg) produced an additional reduction in blood Hcy of 7 %, whereas vitamin B₉ (mean 16·5 mg) did not have any significant effect. Hence, in typical populations, daily supplementation with both 0·5 to 5 mg folic acid and about 0·5 mg vitamin B₁₂ would be expected to reduce Hcy levels by one-quarter to one-third (from about 12 μmol/l to about 8 to 9 μmol/l). Large-scale randomised trials of such regimens are now required to determine whether lowering Hcy levels by folic acid and vitamin B₁₂, with or without added vitamin B₉, reduces the risk of vascular disease.

In this sense, it has also to be considered on one hand that high doses of folic acid may mask the megaloblastic anaemia due to vitamin B₁₂ deficiency seen in elderly individuals as a result of atrophic gastritis. On the other hand, we have to be aware that vitamin B₁₂ status is primarily a determinant of postprandial Hcy levels, but not fasting levels. Thus, in studies of B vitamin supplements and Hcy, it often appears that vitamin B₉ has little effect on Hcy levels because these studies typically only look at fasting Hcy levels.

In addition, it is interesting to consider the issue of folic acid fortification. In the USA and Canada, folic acid fortification of enriched grain products was fully implemented by 1998. Yang et al. (75) evaluated trends in stroke-related mortality before and after folic acid fortification in the USA and Canada and, as a comparison, during the same period in England and Wales, where fortification is not required. They observed a trend consistent with the hypothesis that folic acid fortification is contributing to a reduction in stroke deaths.

Patients with chronic inflammation as well as those with chronic or acute infection are at elevated stroke risk (76). Due to the high prevalence of high Hcy among apparently well-nourished populations and the tendency for Hcy concentrations to increase with age, and the effects of Hcy on stroke risk, lowering the levels of Hcy may have profound implications for public health (77,78). However, according to Robinson (115), the benefit of routine measurement of Hcy concentrations remains speculative until the results of some of the intervention trials become known. In the same sense, Hankey (79) concluded that there is not sufficient evidence to recommend routine screening of plasma Hcy and routine treatment of high Hcy concentrations with vitamins to prevent symptomatic cerebrovascular disease.
Homocysteine

A high Hcy concentration is an independent risk factor for coronary artery disease, stroke, peripheral vascular atherosclerosis, and for arterial and venous thromboembolism, although the mechanisms for this effect remain poorly understood. The association between cognitive function and risk of death from stroke suggests that cerebrovascular disease is an important cause of declining cognitive function. Hcy is believed to cause atherogenesis and thrombogenesis via endothelial damage, focal vascular smooth muscle proliferation probably causing irregular vascular contraction and coagulation abnormalities. The significance of any association between CVD and stroke, and circulating Hcy concentrations is attracting considerable attention. Morris et al. evaluated the association between serum Hcy concentration and self-report heart attack or stroke in adult male and female participants in the Third National Health and Nutrition Examination Survey (NHANES III). The study reported 2-4 times more episodes of heart attack or stroke in men with Hcy concentration of > 12 μmol/l than among individuals with lower values. According to Kuller & Evans, Hcy and B vitamin levels may contribute to the development of vascular disease through mechanisms independent of the atherosclerosis process. In fact, whereas high Hcy levels are directly related to the development of atherosclerosis, a decrease in folate or vitamin B12 and vitamin B6 increases the risk of vascular disease independently of atherosclerosis. High Hcy levels could be associated with an enhancement of inflammatory process and increased risk of thrombosis. Giles et al. found that in a representative sample of US adults, Hcy concentration was independently associated with an increased likelihood of non-fatal stroke, and this association was present in both black and white adults. In a different study, Perry et al. measured serum Hcy levels in 107 cases and 118 control males, matched for age and other variables. The association between serum Hcy concentration and stroke was present in both black and white adults. In a different study, Perry et al. measured serum Hcy levels in 107 cases and 118 control males, matched for age and other variables. The association between serum Hcy concentration and stroke was present in both black and white adults.

A high concentration of Hcy appears to have significant effect on platelets’ function and it may be relevant to blood–brain barrier changes. The neurotoxicity of Hcy acting through the overstimulation of N-methyl-D-aspartate receptors could be one of the mechanisms that contribute to neuronal damage in high Hcy. In addition to a possible direct pathological effect of Hcy on the endothelium, elevated Hcy levels lead to the development and progression of vascular disease by affecting platelets’ function and aggregation. Mutus et al. showed that Hcy-induced inhibition of NO production in platelets was lower in platelets from diabetic patients than in platelets from control subjects. Other studies have suggested that moderate to high Hcy levels play a role in the development of a thrombogenic state through oxidative stress-mediated insult.

High Hcy levels are also associated with atherosclerosis, thromboembolism and vascular endothelial cell injury. The effect of Hcy in developing thrombosis may be associated with an inhibitory action on endothelial cell thrombomodulin expression, which was independent of platelet aggregation or heparin cofactor activity. In severe high homocysteinaemia, circulating endothelial cells have been detected, indicative of endothelial cell death. Also, Hcy induces apoptosis in human umbilical vein endothelial cells by activation of the unfolded protein response. In the same way, Hcy-thiolactone induced endothelial cell apoptosis in a concentration-dependent manner with concentrations that ranged from 50 to 200 μmol/l, independently of the caspase pathway. Wang et al., using a concentration that overlaps clinically, observed levels of 10–50 μmol/l Hcy per litre, inhibited DNA synthesis in vascular endothelial cells and arrested their growth at the G1 phase of the cell cycle. Chambers et al. detected endothelial dysfunction at Hcy concentrations similar to those associated with increased risk of myocardial infarction and stroke. Interestingly, pre-treatment of cells with vitamin C prevented the decrease in flow-mediated dilatation after methionine. Thus, elevation of Hcy concentration appears to be associated with an acute impairment of vascular endothelial cell function that can be prevented by pre-treatment with vitamin C in healthy subjects. Another important finding is the molecular association between the atherosclerotic process and high Hcy. Li et al. using a cDNA microarray, found an unexpected link between Hcy and cholesterol dysregulation with increased levels of 3-hydroxy-3-methylglutarl coenzyme A reductase mRNA and protein in endothelial cells, suggesting a possible role of Hcy-induced changes in endothelial cells. Interestingly, the use of statins improved endothelial NO production in Hcy-treated endothelial cells. To study the mechanisms by which Hcy may promote vascular modifications, Kokame et al. applied a non-radioactive differential display analysis to evaluate changes in gene expression induced by Hcy in human umbilical vein endothelial cell culture. They identified six up-regulated genes and one down-regulated gene, revealing that Hcy alters the expression of multiple proteins, some of them associated with the endoplasmic reticulum stress response. Oitinen et al. demonstrated using human umbilical endothelial cells that Hcy causes adverse effects on the endoplasmic reticulum, altering the expression of several genes sensitive to endoplasmic reticulum stress. They also showed that Hcy altered various genes known to mediate cell growth and differentiation. In addition, they observed that Hcy altered the gene profile involved in the expression of cellular proteins such as glutathione peroxidase and superoxide dismutase, thus potentially enhancing the cytotoxic effects of agents or conditions known to cause oxidative damage. Another study using human endothelial cells demonstrated that Hcy may act upon the vasculature through activation of kinases such as Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK), and subsequent expression of transcription factor ATF3 involved in the regulation of synthesis of proteins critical for endothelial cell function.
human aortic endothelial cells exposed to as little as 10 μM-DL-Hcy up-regulated the expression of chemokines such as monocyte chemoattractant protein-1 (MCP-1) and IL-8. Maximal expression was achieved with 50 μM-DL-Hcy within 2–4 h of incubation. This suggests that Hcy may contribute to the initiation and progression of vascular disease by promoting leucocyte recruitment. Holven et al. (115) suggested that Hcy exerts its atherogenic effects in part by enhancing chemokine expression in cells involved in atherosogenesis and that folic acid supplementation may down-regulate these inflammatory responses. On the other hand, the recruitment of monocytes is an important event in atherogenesis. MCP-1 is a potent chemokine that stimulates monocyte migration into the intima of arterial walls. In the hand, the recruitment of monocytes is an important event in atherogenesis. MCP-1 is a potent chemokine that stimulates monocyte migration into the intima of arterial walls. In the same manner, Wang et al. (116) investigated the effect of Hcy on MCP-1 expression in macrophages and the underlying mechanism of this effect. They demonstrated that Hcy, at pathological concentration, stimulates MCP-1 expression in human monocyctic cell macrophages via NF-κB activation. Also, in this sense, another study demonstrated that Hcy might increase monocyte recruitment into developing atherosclerotic lesions by up-regulating MCP-1 and IL-8 expression in vascular smooth muscle cells (117). In addition, a study demonstrated that Hcy inhibits TNF-α-induced activation of the endothelium via the modulation of NF-κB activity. These results indicate that Hcy alters the response to injury of endothelial cells, which may have fundamental impacts on mechanisms of leucocyte recruitment to sites of inflammation. These findings may indicate a novel pathway by which Hcy is involved in vascular disorders associated with homocystinuria (118).

Antioxidant vitamins E and C

Vitamins E and C have been investigated in a large number of epidemiological, clinical and experimental studies (119–121). Antioxidant nutrients have important roles in cell function and have been implicated in processes associated with ageing, including vascular, inflammatory and neurological damage. The evidence regarding the link between vitamin E deficiency and neurological sequelae in man is now firmly established. That several neuropathological observations are associated with vitamin E deficiency indicates the importance of this nutrient in the central nervous system for normal neurological function (122–124). Vitamin E’s protective effect against cognitive decline and neurodegenerative disease has been explored in several epidemiological and clinical studies during the last decade (125,126). When plasma antioxidants and cognitive performance in middle-aged and older adults were measured in the Austrian Stroke Prevention Study, vitamin E was found to be significantly associated with cognitive functioning (127). Rosénblum et al. (128) reported a protective effect by vitamin E to ameliorate the adverse effects of endothelial cell injury from brain ischaemia.

Recent studies have shown that increased vitamin E intake slows the progression of dementia and may improve central nervous system function. A study evaluated the intake of antioxidants and the risk of stroke, providing evidence that vitamin E might be of value in reducing the risk of stroke. This study looked at the diets of over 34 000 postmenopausal women as well as their risk of death from stroke (224). A total of 215 of the women died of strokes during the study period. Interestingly, the paper noted that the greater the amount of vitamin E in the diet, the lower the risk of death from stroke (224). There was a suggestion of an inverse association between specific foods rich in vitamin E and death from stroke. However, these authors found no reduction in risk of death from stroke with vitamin E supplements, which might indicate that vitamin E intake was in fact a surrogate marker for some other protective agents in the diet.

Prospective studies that examined the association between vitamin E intake and death from stroke have produced conflicting results. This is an important area of research that still remains poorly studied because in most of the studies there is no detailed information of the dose, frequency and time that these subjects were taking vitamin E supplements. However, the Health Professionals Follow-Up Study looked at nearly 44 000 men aged 40–75 years without known heart disease or diabetes, and measured the incidence of stroke, including deaths and all occurrences of strokes, and compared it with the participants’ intake of various antioxidants (17). They also found no reduction in the incidence of stroke in those who took antioxidant supplements. A study conducted in Helsinki, Finland, looked at nearly 30 000 male smokers for 6 years (18). Participants were assigned to take supplements of vitamin E, β-carotene or placebo. More than 1000 suffered strokes during the study period. Of those, fewer than 200 had the type of stroke caused by leaking blood vessels in the brain, and about 800 had the sort of stroke caused by blockage of blood vessels from atherosclerosis. The researchers found that taking vitamin E supplements increased the risk of strokes from bleeding in the brain among smokers, but decreased the risk of strokes caused by atherosclerosis in those participants who had high blood pressure. Strokes from atherosclerosis also decreased among the diabetics who took vitamin E supplements, with no associated increased risk in bleeding strokes (18,129). Thus, the researchers concluded that vitamin E supplementation may prevent ischaemic stroke in high-risk hypertensive patients, but further studies are needed. Results from a study on vitamin supplements, reported at the 51st annual meeting of the American Academy of Neurology in Toronto (130), showed that supplements containing even modest amounts of vitamin E are protective against ischaemic stroke. This study shows that vitamin E supplements can reduce stroke risk by 53%. The total vitamin E intake of 27 IU/d (18 mg/d) was significantly lower in subjects who had sustained an ischaemic stroke than in individuals who had not had a stroke – their mean total daily intake was 58 IU/d (38-7 mg/d). Also, controls who had not had a stroke were also twice as likely to take a vitamin supplement compared with stroke patients.

Megadoses of vitamin E appear to significantly reduce the levels of inflammation. Devaraj & Jialal (131) studied forty-seven men and women with adult-onset, or type 2, diabetes and twenty-five healthy volunteers. They received 1200 IU (800 mg) vitamin E daily for 3 months. Before treatment, individuals with diabetes produced about two-fold as much C-reactive protein compared with the healthy individuals,
and individuals with mild diabetes showed about 33 %
higher C-reactive protein levels compared with healthy
volunteers. Interestingly, vitamin E supplementation
lowered C-reactive protein levels. In addition, these authors also
reported that, after taking vitamin E, cells from the
volunteers produced about 70 % less IL-6 as was generated
by cells from blood drawn before taking vitamin E.

Hodis et al.\(^{(132)}\) report results from the Vitamin E
Atherosclerosis Progression Study (VEAPS), a randomised
clinical trial designed to determine the effects of DL-\(\alpha\)-tocopherol
supplementation on subclinical atherosclerosis
progression in healthy low-risk individuals. They concluded
that in well-nourished healthy vitamin E-replete individuals
at low risk for CVD, vitamin E supplementation has no
perceptible effect on the progression of atherosclerosis.

Other studies re-examined the preventive role of taking
vitamin E or an inactive placebo for 3 years in men and
women over the age of 40 years\(^{(133,134)}\). Those taking
vitamin E had the same amount of plaque build-up on their
arteries as those taking placebo. The authors concluded that
because the study lasted only 3 years, it cannot be ruled out
that vitamin E might confer a protective effect in
determining taking it for a longer period of time. In addition, the vitamin
E might be beneficial in individuals with kidney disease or
diabetes, who are at increased risk for developing heart
disease.

Another study found that in patients with vascular disease
or diabetes mellitus, long-term vitamin E supplementation
does not prevent cancer or major cardiovascular events and
may increase the risk for heart failure\(^{(135)}\). Miller et al.\(^{(136)}\)
performed a meta-analysis of the dose–response relation-
ship between vitamin E supplementation and total mortality
by using data from randomised, controlled trials. They found as limitations that high-dosage (>400 IU/d;
>267 mg/d) trials were often small and were performed in
patients with chronic diseases. Hence, the generalisability of
the findings to healthy adults is uncertain. As conclusion,
they affirm that high-dosage (>400 IU/d; >267 mg/d) vitamin E supplements may increase all-cause mortality and
should be avoided.

Although some authors have agreed with previous
findings of questionable effects of vitamin E, other studies show a strong association between dietary vitamin E intake and risk of stroke, with a distinctive protective role in
diabetes and atherosclerosis. In addition, the long-term
effect of increasing vitamin E intake by using supplements
remains to be determined. In general, studies on vitamin E
and risk of stroke suggest that in women, dietary intake of
vitamin E is protective, but the role of supplements remains
contradictory and while some authors have reported some
benefits, others were unable to confirm these results.

However, vitamin E supplements may be of benefit to
individuals at higher risk of stroke, due to high blood
pressure or diabetes.

Vitamin C is capable of essentially influencing the course
of many metabolic processes, and it is therefore used in
the treatment and prophylaxis of many diseases, including
processes associated with reactive oxygen species and
oxidative stress. Therefore, because it appears that free
radicals are relevant molecules associated with vascular
pathologies, some studies have focused on the possibility of
using vitamin C to lower or eliminate these molecules. In
addition, vitamin C plays significant roles at the molecular
level as a cofactor for several enzymes involved in the
biosynthesis of collagen, carnitine and neurotransmitters.
In fact, some studies have suggested the administration of
vitamin C in the treatment of patients with coronary arterial
disease, treatment of patients after cardiac infarction or cere-
bral stroke, or in the treatment of arterial hypertension\(^{(137)}\).

Plasma vitamin C concentration has also been found to be
positively associated with cognitive function\(^{(138)}\). Vitamin C
(ascorbic acid) is an extremely effective antioxidant that has
been demonstrated to have potent antioxidant actions in
human plasma and is associated with an 11 % reduction in
stroke prevalence\(^{(21,139,140)}\). Vitamin C has been shown to
significantly improve endothelium-dependent vasodilata-
 tion in diabetics and patients with coronary artery disease,
perhaps by reducing excess superoxide production, and
thereby decreasing the levels of NO inactivation\(^{(141)}\).

Interestingly, there are no studies documenting the role
that vitamin C may have in preventing stroke-mediated
endothelial cell dysfunction. Antioxidant vitamins E and C
may be capable of improving vascular function, quieting
activated glial cells in the brain, and/or reducing the
oxidative-mediated damage, which may be relevant to
ameliorating or preventing the damage caused to neuron
cells by circumscribed inflammatory processes\(^{(142–144)}\).

Although clinical trials have shown no significant benefit
of vitamin C supplementation in reducing stroke risk, they
were not able to examine the relationship between plasma
vitamin C concentrations and stroke risk in a general
population. Some studies have indicated that vitamin C may
have some role in modulating hypertension, an important
risk of stroke. A study by Kurl et al.\(^{(145)}\) examined whether
plasma vitamin C modifies the association between
overweight, hypertension and the risk of stroke in middle-
aged men from eastern Finland. Interestingly, low plasma
vitamin C was associated with an increased risk of stroke,
especially among hypertensive and overweight men. The
recent study by Myint et al.\(^{(146)}\) examined the relationship
between baseline plasma vitamin C concentrations and risk
of incident stroke in a British population. The study was
conducted in 20,649 men and women aged 40–79 years
without prevalent stroke at baseline and participating in the
European Prospective Investigation into Cancer-Norfolk
prospective population study. The participants completed a
health questionnaire and attended a clinic between 1993 and
1997, and were followed up for incident strokes through to
March 2005. This study concluded that plasma vitamin C
concentrations may serve as a biological marker of lifestyle
or other factors associated with reduced stroke risk and may
be useful in identifying those at high risk of stroke.

Data regarding the effects of general nutritional status on
stroke risk are limited. There is no evidence that the use of
dietary vitamin E or C supplements or the use of specific
carotenoids substantially reduces the risk of stroke\(^{(147)}\).

An analysis of data from the Nurses’ Health Study and the
Health Professionals Follow-Up Study that included
individuals free of CVD at baseline found that the relative
risk of stroke was 0.69 (95 % CI 0.52, 0.92) for individuals
in the highest quintile of fruit and vegetable intake\(^{(147)}\).
An increment of one serving per d was associated with a 6% lower risk of stroke. However, it cannot be certain whether the effect was specifically due to diet or a reflection of a generally healthier lifestyle in these individuals.

On the other hand, it has been documented that there is a protective relationship between the consumption of green leafy vegetables, citrus fruit and juice, and ischaemic stroke risk. Randomised trials have largely failed to support an effect of antioxidant vitamins on the risk of CVD. Few trials have examined interactions among antioxidants. The Women’s Antioxidant Cardiovascular Study tested the effects of ascorbic acid (500 mg/d), vitamin E (600 IU (400 mg) every other day) and β-carotene (50 mg every other day) on the combined outcome of myocardial infarction, stroke, coronary revascularisation, or CVD death among 8171 female health professionals at increased risk in a 2 × 2 × 2 factorial design. Participants were aged 40 years or older with a history of CVD or three or more CVD risk factors and were followed up for a mean duration of 9.4 years, from 1995–6 to 2005. There were no significant interactions between agents for the primary end point, but those randomised to both active ascorbic acid and vitamin E experienced fewer strokes.

Ullegaddi et al. (149) carried out a randomised controlled trial to test whether supplementary antioxidants immediately following acute ischaemic stroke will enhance antioxidant capacity and mitigate oxidative damage, concluding that supplementation with antioxidant vitamins (800 IU (727 mg) α-tocopherol and 500 mg vitamin C for 14 d) within 12 h of onset of acute ischaemic stroke increased antioxidant capacity, reduced lipid peroxidation products and may have an anti-inflammatory effect. Therefore, it is very important to investigate the levels of vitamins E and C in relation to levels of cytokines, vascular alterations, and brain changes, and their association with cognition. The stroke-associated changes in brain vasculature, namely the development of metabolic and functional changes in the brain associated with impaired cognitive abilities, is caused by the development of an inflammatory response following stroke. Products of inflammatory reactions, such as cytokines, and adhesion molecules, therefore, may represent extracellular signals that initiate neuronal degeneration through several intracellular signals. Micronutrient deficiency will contribute, extending the cellular events to the cognitive impairment elicited by the ischaemic insult to the brain.

Oxidative stress

Oxidative stress in stroke patients has been discussed in many studies, and the results of these studies remain contradictory (49, 150–157). Experimental studies have provided evidence of an association between ischaemic stroke and increased oxidative stress. In fact, Cherubini et al. (138) reported a significant reduction in several antioxidants immediately after an acute ischaemic stroke, possibly as a consequence of increased oxidative stress. A specific antioxidant profile is associated with a poor early outcome. Attention has recently focused on the measurement of F2-isoprostanes as a sensitive and specific index of oxidative stress. F2-isoprostanes are a family of eicosanoids of non-enzymic origin produced by the random oxidation of tissue phospholipids by oxygen radicals. Several reports have indicated that isoprostanes are elevated by oxidative stress. F2-isoprostanes have been proposed as markers of antioxidant deficiency and oxidative stress, and elevated levels have been reported in Alzheimer’s disease and heavy smokers (159, 160). Recently, the authors performed a case–control study of consecutive ischaemic stroke patients presenting within 8 h of stroke onset. In fifty-two cases and twenty-seven controls, early (median 6 h post-onset) F2-isoprostanes were elevated in stroke cases compared with controls and early plasma F2-isoprostanes correlated with metalloproteinase-9 in all patients (P = 0.01). The study concluded that in early human stroke evidence has been found of increased oxidative stress and a relationship with metalloproteinase-9 expression, supporting findings from experimental studies (161). In another study, plasma levels of F2-isoprostanes were significantly elevated in the stroke patients compared with the control subjects (P = 0.02) (162). Interestingly, in the study by Sánchez-Moreno et al. (162) an inverse correlation between plasma vitamin C concentration and F2-isoprostane levels in the stroke patients, as well as a positive correlation between C-reactive protein and F2-isoprostane levels were reported. This finding suggests that antioxidants may play a very important role in modulating the levels of inflammatory markers and consequently reduce the cognitive impairment changes associated with stroke.

Some epidemiological studies have reported on the effects of lipid peroxidation and antioxidant status on atherosclerosis and risk for stroke. In a recent study, serum levels of NO, malondialdehyde and glutathione were significantly elevated in acute stroke patients (163). Other groups have evaluated this question by assessing the levels of thiobarbituric acid-reactive substances and analysed their relationship with antioxidant status and ultrasonographically assessed carotid atherosclerosis. A longitudinal study on cognitive and vascular ageing (Etude sur le Vieillissement Arteriel; the EVA Study), composed of 1187 men and women aged 59–71 years without any history of coronary artery disease or stroke, examined the intima-media thickness (IMT) on the common carotid arteries (CCA) and at the site of plaques (164). After adjustment for conventional cardiovascular risk factors, erythrocyte vitamin E was significantly and negatively associated with CCA-IMT in both men and women. Interestingly, although no association was found between thiobarbituric acid-reactive substances and CCA-IMT in either sex, thiobarbituric acid-reactive substances were significantly higher in men with carotid plaques than in those without (164). Furthermore, this association was strengthened in men with concentrations of erythrocyte plasma vitamin E below the lowest quartile.

Conclusions

A large body of evidence suggests that intake of folate and B vitamins may be beneficial in stroke prevention by reducing levels of plasma Hcy; however, limited information is available regarding dietary intake of vitamins or use of...
vitamin supplements by stroke patients. Several studies are in progress to determine whether treatment with folic acid in combination with vitamins B₆ and B₁₂ will reduce the risk of stroke in patients with increased serum Hcy. Hcy is believed to cause atherogenesis and thrombogenesis via endothelial damage, focal vascular smooth muscle proliferation probably causing irregular vascular contraction, and coagulation abnormalities. Therefore, the significance of any association between CVD and stroke, and circulating Hcy concentrations is attracting considerable attention.

Antioxidant nutrients have important roles in cell function and have been implicated in processes associated with ageing, including vascular, inflammatory and neurological damage. Prospective studies that examined the association between vitamin E intake and death from stroke have produced conflicting results. This is an important area of research that still remains poorly studied because in most of the studies there is no detailed information of the dose, frequency and time that these subjects were taking vitamin E supplements. In general, studies on vitamin E and risk of stroke suggest that in women, dietary intake of vitamin E is protective, but the role of supplements remains contradictory and while some authors have reported some benefits, others were unable to confirm these results. However, vitamin E supplements may be of benefit to individuals at higher risk of stroke, due to high blood pressure or diabetes. Plasma vitamin C concentration has also been found to be positively associated with cognitive function. Plasma vitamin E and C concentrations may serve as a biological marker of lifestyle or other factors associated with reduced stroke risk.

As a general conclusion we can affirm that epidemiological associations and results of intervention studies suggest that low B vitamin status, elevated blood Hcy and low antioxidant status are risk factors for stroke. After reviewing the observational and intervention studies, there is an incomplete understanding of mechanisms and some conflicting findings; therefore the available evidence is insufficient to recommend the routine use of B vitamins, vitamin E and vitamin C for the prevention of stroke. A heart-healthy diet, emphasising fruits and vegetables containing B vitamins and antioxidants, may be the best recommendation. Further well-designed controlled clinical trials are necessary so that the detailed requirements of these individuals can be better understood.
