Abstract

The objective of the present study was to investigate whether a previously reported apparent negative relationship between fat mass and daily physical activity in Japanese adult women would also be observed in Japanese adult men. The subjects were grouped into quartiles of BMI and body fat percentage (%BF). The number of steps walked each day and the duration of light- to vigorous-intensity physical activity were assessed by an accelerometer over the same period of time as for the doubly labelled water experiment. The results showed that BMI negatively correlated with the number of steps and time spent in moderate-intensity physical activity, whereas %BF showed a negative relationship with physical activity-related energy expenditure (PAEE)/body weight (BW) and physical activity level. The analysis of data using %BF quartiles revealed that PAEE/BW decreased from the second quartile in which the BMI was 25 kg/m². These observations are similar to those reported in our previous study in Japanese adult women. These cross-sectional studies cannot prove causality, and that obesity causes physical inactivity may be the case. However, the results of the present study provide information regarding which physical activity variables should be used in longitudinal studies.

Key words: Body composition; Physical activity; Doubly labelled water; Accelerometry; Japanese adult men

The prevalence of obesity is rising rapidly in most Asian countries, especially in Japan with an increase of 46% from 1976–80 to 2000(1). Specifically, the overall prevalence of overweight and obese adult men in Japan has increased gradually over the past 20 years, whereas the prevalence of overweight and obese adult women has not changed(2). Obesity is commonly caused by an energy imbalance, with low total energy expenditure (TEE) possibly being a contributing factor in this process. While a negative relationship between obesity and daily physical activity has been reported(3,4), the majority of studies have not observed this relationship(5,6). Therefore, the relationship between BMI (body weight (BW, kg) divided by height squared (m²)) and daily physical activity still remains unclear.

In studies using the doubly labelled water (DLW) method, the most accurate method for measuring TEE in free-living conditions(7,8), the majority of Western adult populations showed no relationship between BMI and physical activity level (PAL, the ratio of TEE:RMR)(9–11).

On the other hand, we have recently reported that Japanese adult women with higher fat deposition had higher body fat percentage (%BF) with an apparent lower PAL compared with those with lower fat deposition(12). However, this association was not observed when women were categorised using BMI. In addition,
step counts or time spent in moderate- or vigorous-intensity physical activity assessed by an accelerometer (i.e. the part composed of PAL) was also found to be lower in women with higher fat deposition\(^{(12)}\).

However, Westerterp & Goran\(^{(13)}\) using a meta-analysis of data of 290 adults from twenty-two DLW studies reported that a higher PAL was related to a lower fat mass (FM) only in men but not in women. This indicates that the relationship between physical activity and fat deposition may be different between the sexes. However, this relationship was not observed if data were stratified according to BMI.

The main aim of the present study was to examine whether the negative relationship that we observed between %BF and daily physical activity in our previous cross-sectional study in Japanese adult women\(^{(12)}\) was also apparent in Japanese adult men. Information from the present study will help to understand the role of daily physical activity in the increased prevalence of obesity in adult males.

**Methods**

**Subjects**

Participants were recruited through health-care centres or at workplaces in three urban districts in central and western Japan, as described previously\(^{(12)}\). In each location, subjects were included for the study according to the following criteria: (1) in good health; (2) not involved in hard physical labour such as farming or athletics; (3) BMI >18·5 kg/m\(^2\); (4) living in their home prefecture 2 weeks before and during the study; (5) not on a weight-loss or treatment diet; (6) alcohol consumption <40 g/d. The occupations of the participants were mainly salesmen, teachers, clerks and desk jobs, and some were unemployed. Overall, eighty-five male subjects aged 30–69 years were selected for the study. Over the entire assessment period, subjects were instructed to carefully maintain their normal daily activities and eating patterns and to make no conscious effort to lose or gain weight. The present study was conducted according to the guidelines laid down in the Declaration of Helsinki, and all procedures involving human subjects were approved by the Ethical Committee of the National Institute of Health and Nutrition in Japan. Written informed consent was obtained from all subjects.

**Experimental procedures**

The experimental design has been described in detail in our previous study\(^{(12)}\). Briefly, urine samples were collected and BW and height measured on the day before the assessment of physical activity (day 0). RMR was measured in the supine position using a Douglas bag in the early morning 12 h or longer after the last meal. A single dose of DLW was then given orally to each subject. After administration of this dose, the participants were instructed to collect urine samples on the following day and at eight additional times at the same time of the day during the 2-week study period. On day 15, BW and height were measured again to examine changes in BW during the study period. The subjects were then provided with an accelerometer and a self-administered diet history questionnaire. Daily physical activity was estimated over the same 2-week study period under free-living conditions using the DLW method and accelerometer.

**Measurement of energy expenditure and body composition**

We measured TEE using the DLW method, as described previously\(^{(12)}\). Briefly, the single dose of DLW consisted of approximately 0·06 g/kg BW of \(^2\)H\(_2\)O (99·8 atom%; Cambridge Isotope Laboratories) and 1·4 g/kg BW of \(^2\)H\(_2\)O (100·0 atom%; Taiyo Nippon Sanso). Isotopic enrichment of urine samples was measured using an isotope ratio mass spectrometer (model DELTA Plus; Thermo Electron Corporation). The \(^2\)H and \(^18\)O zero-time intercepts and elimination rates \((k_0\) and \(k_e\)) were calculated using least-squares linear regression of the natural logarithm of the isotope concentration as a function of the elapsed time from dose administration. The zero-time intercepts were used to determine isotope pool sizes. Total body water was calculated as the mean value of the isotope pool size of \(^2\)H divided by 1·041 and that of \(^18\)O divided by 1·007. Fat-free mass (FFM) was calculated by assuming a hydration of 0·732\(^{(14)}\). FM was calculated as BW minus FFM, while %BF was computed from BW and FFM. Calculation of TEE (kJ/d) was performed using the modified Weir formula\(^{(15)}\) based on the CO\(_2\) production rate and respiratory quotient. Food quotient calculated from the diet history questionnaire was used instead of the respiratory quotient. This assumes that under conditions of perfect nutrient balance, the food quotient must equal the respiratory quotient\(^{(16,17)}\). PAL was estimated by dividing TEE by RMR. Physical activity-related energy expenditure (PAEE) was calculated as 0·9 × TEE ~ RMR, assuming that the thermic effect of food was 10% of TEE\(^{(18)}\).

**Other measurements**

Measurements of anthropometry, accelerometry and the diet history questionnaire have been described in detail in our previous study\(^{(12)}\). Briefly, a uniaxial accelerometer (Lifeorder EX; Suzuken Company Limited) was used for measuring the intensity of physical activity and step counts. The intensity of physical activity every 2 min was classified as either light (<3 metabolic equivalents), moderate (3 to <6 metabolic equivalents) or vigorous (≥6 metabolic equivalents)\(^{(16)}\). The validation and methodology of the diet history questionnaire have been described in detail elsewhere\(^{(17)}\).

**Statistical analysis**

Data are presented as means and standard deviations. BMI was calculated as BW (measured before the DLW dose) divided by height squared (kg/m\(^2\)). The associations between physical activity and BMI or %BF, expressed as continuous variables, were examined by the linear regression analysis with or without adjustment for covariates. Subjects were then grouped according to quartiles of BMI and %BF. A one-way ANOVA or ANCOVA was used to compare the variables in the quartiles, with Fisher's least-square difference used as

TEE, total energy expenditure; PAL, physical activity level (TEE/RMR); PAEE, physical activity-related energy expenditure (0·9 £ TEE – RMR); BW, body weight; MET, metabolic equivalents.

There was a significant correlation with BMI: *P<0·05, **P<0·01.

Mean values were significantly different from those of the first quartile: †P<0·05, ††P<0·01.

Mean values were significantly different from those of the second quartile: ‡P<0·05.

Mean values were significantly different from those of the third quartile: §P<0·05.

The subjects were categorised by quartile. The number of subjects in each quartile was twenty-five. In the nine intensity levels (1–9) of physical activity assessed by using an accelerometer, 1–3 indicates light intensity, 4–6 moderate intensity and 7–9 vigorous intensity.

The associations between BMI and physical activity variables and energy expenditure components, expressed as continuous variables, were examined by the linear regression analysis.

There was no significant difference between BMI and PAEE after adjustment for BW (partial r = 0·046, P=0·677).
a post hoc test for multiple comparisons. Differences were considered statistically significant when the \( P \) value was \(<0.05\). All statistical analyses were carried out using SPSS for Windows (version 16.0 J; SPSS, Inc.).

Results

Of the total eighty-five men studied, the proportion of normal-weight (BMI \( 18.5 \) to \(<25 \text{ kg/m}^2 \)), overweight (BMI \( \geq 25 \) to \(<30 \text{ kg/m}^2 \)) and obese participants (BMI \( \geq 30 \text{ kg/m}^2 \)) was 54.1, 35.3 and 10.6%, respectively. The mean age of the subjects was 47.5 (SD 11.0, range 30–69) years. The mean BW, height and BMI were 73.5 (SD 14.0, range 51.1–116.3) kg, 1.70 (SD 0.07, range, 1.51–1.88) m and 25.3 (SD 3.9, range 18.7–39.1) kg/m\(^2\), respectively. BW did not change during the study (change in BW: \( -0.13 \) (SD 0.04) kg, \( P=0.987 \)). The range of PAL was 1.46–2.51 with a mean value of 1.98.

The relationships between BMI and energy expenditure or physical activity variables are shown in Table 1 and Fig. 1. Both FM \( (r=0.824) \) and FFM \( (r=0.714) \) showed a linear correlation with BMI. TEE increased linearly with BMI, whereas PAEE/BW, step counts and moderate-intensity physical activity showed a negative correlation. PAL and PAEE adjusted for BW did not correlate with BMI (Fig. 1).

Energy expenditure and physical activity variables were also compared between the BMI quartiles. Age and height were not significantly different between the quartiles. TEE, step counts and moderate-intensity physical activity were significantly different between the quartiles. The fourth quartile had significantly smaller PAEE/BW, step counts and moderate-intensity PAL compared with the other three quartiles. A statistically significant decrease in TEE between the BMI quartiles was still observed after adjustment for BW using ANCOVA \( (P=0.026) \). However, PAEE did not show any significant difference between the BMI quartiles after adjustment for BW using ANCOVA \( (P=0.155) \).

PAL, PAEE/BW and moderate-intensity physical activity showed a negative correlation with %BF (Table 2; Fig. 1). FM increased with %BF \( (r=0.876) \), whereas FFM did not \( (r=0.008) \). As shown in Fig. 1, after PAEE was adjusted for BW, a negative correlation was still observed between PAEE and %BF. A statistically significant difference was found between the %BF quartiles for PAL, PAEE/BW, step counts and moderate- and vigorous-intensity physical activities. A significant difference in TEE and PAEE was still found between the %BF quartiles after adjustment for BW using ANCOVA \( (P=0.001 \) and 0.002). PAEE was lower in the second and fourth quartiles than in the first quartile when it was adjusted for BW using ANCOVA. PAL was lower in the second and fourth quartiles than in the first quartile, whereas there was no significant difference between the second and fourth quartiles.

Discussion

The present study aimed at comparing the relationship of BMI and %BF with various aspects of daily physical activity between Japanese adult men investigated in the present study and Japanese adult women that we have reported.

Mean values were significantly different from those of the first quartile: †P < 0.05, ‡P < 0.01, §P < 0.001.

No significant correlation was observed between BMI and PAEE. However, the PAL was negatively related to BMI. The PAL negatively correlated with both PAL and PAEE. In particular, a significant relationship was still found between BMI and PAEE after adjustment for BW as a covariate. Therefore, the present study showed that there was no significant relationship between BMI and PAEE, following adjustment for BW as a covariate. Despite the convenience of correcting for body size, dividing PAEE by BW should be interpreted with caution, as this may be subject to artifacts due to problems with a zero intercept or the requirement of proportionality.
relationship between step counts and BMI in Japanese adult women, but not in men. This discrepancy in the relationship between BMI and step counts in Japanese subjects may be attributable to lower BW, BMI and step counts in the study by Mitsui et al.\textsuperscript{(25)}. Thus, physical activity variables assessed by an accelerometer may be useful for understanding daily physical activity in obese adult populations in large epidemiological studies.

On the other hand, time spent in moderate-intensity physical activity was significantly related to %BF in men, although this relationship was not observed in women\textsuperscript{(12)}. Conversely, the number of steps was related to %BF not in men but in women. The reason for this discrepancy between the sexes was not clear, although it is possible that %BF may be related to the total energy expended in daily physical activity rather than to the part composed of PAEE or PAL that included the number of steps and exercise intensity.

The present study is limited by the cross-sectional study design, which makes it difficult to clarify the causality between obesity and physical inactivity. Therefore, we cannot exclude the possibility of reverse causality that obesity may cause physical inactivity. For example, obese subjects fatigue after taking a few steps because they have to propel a larger mass, as a result, the lowered physical activity may cause obesity\textsuperscript{(26)}. In line with this, men in the fourth quartile, almost obese, may have had less volitional movement during physical activity due to their excess weight. The possibility of reversal causality is in agreement with the longitudinal study by Luke et al.\textsuperscript{(29)} demonstrating that physical inactivity on the basis of energy expenditure does not predict weight change.

The present study also has the following limitations. First, FFM hydration was assumed to be equal in all participants at a value of 0.732\textsuperscript{(14)}, therefore, some errors in estimating FM obtained from FFM may have resulted from differences in the levels of obesity and sex. Second, PAL in the study was higher than 1.75, the value reported in the general population of Eastern and Western countries\textsuperscript{(21,26–28)}. The average daily number of steps of about 9564 observed in the participants of the present study was also higher than that reported for Japanese adult men in another study, who generally walk an average of 7893 steps/day\textsuperscript{(29)}. This indicates that the individuals included in the present study may have been more physically active than adult men in the general Japanese population. However, the ranges of PAL were similar between men and women (1.46–2.51 and 1.36–2.52, respectively)\textsuperscript{(12)}, which were within the PAL of the general population\textsuperscript{(30)}.

In conclusion, the present cross-sectional study in Japanese adult men showed a negative relationship between BMI and the number of steps and time spent in moderate-intensity physical activity. It also showed that men with higher fat deposition were less active on the basis of PAEE adjusted for BW and PAL. These observations are very similar to those reported in our previous study in adult Japanese women\textsuperscript{(12)}. These cross-sectional studies cannot prove causality, and that obesity causes physical inactivity may be the case. Despite these limitations, the present study did provide information regarding which physical activity variables are appropriate for use in a longitudinal study. Additional research using a longitudinal study design is required to examine the cause–effect relationships between obesity and physical inactivity including factors of dietary intake.
