Abstract

Deoxynivalenol (DON) and fumonisins (FB) are mycotoxins produced by Fusarium species, which naturally co-occur in animal diets. The gastrointestinal tract represents the first barrier met by exogenous food/feed compounds. The purpose of the present study was to investigate the effects of DON and FB, alone and in combination, on some intestinal parameters, including morphology, histology, expression of cytokines and junction proteins. A total of twenty-four 5-week-old piglets were randomly assigned to four different groups, receiving separate diets for 5 weeks: a control diet; a diet contaminated with either DON (3 mg/kg) or FB (6 mg/kg); or both toxins. Chronic ingestion of these contaminated diets induced morphological and histological changes, as shown by the atrophy and fusion of villi, the decreased villi height and cell proliferation in the jejunum, and by the reduced number of goblet cells and lymphocytes. At the end of the experiment, the expression levels of several cytokines were measured by RT-PCR and some of them (TNF-α, IL-1β, IFN-γ, IL-6 and IL-10) were significantly up-regulated in the ileum or the jejunum. In addition, the ingestion of contaminated diets reduced the expression of the adherent junction protein E-cadherin and the tight junction protein occludin in the intestine. When animals were fed with a co-contaminated diet (DON + FB), several types of interactions were observed depending on the parameters and segments assessed: synergistic (immune cells); additive (cytokines and junction protein expression); less than additive (histological lesions and cytokine expression); antagonistic (immune cells and cytokine expression). Taken together, the present data provide strong evidence that chronic ingestion of low doses of mycotoxins alters the intestine, and thus may predispose animals to infections by enteric pathogens.

Key words: Multi-contamination: Mycotoxins: Deoxynivalenol: Fumonisins: Intestine: Cellular junctions: Immunity

Mycotoxins are secondary metabolites of various fungi commonly found in feed and foodstuffs. Based on their known and suspected effects on human and animal health, aflatoxin, fumonisin, deoxynivalenol, ochratoxin A and zearalenone are recognised as the five most important agricultural mycotoxins(1). The toxic effects of Fusarium mycotoxins in animals include reduced growth, feed refusal, immunosuppression, gastrointestinal lesions, and neurological and reproductive disorders(2).

Recent surveys(3,4) have demonstrated the regular occurrence of low levels of multiple mycotoxins in cereals. The toxicity of combinations of mycotoxins cannot always be predicted based upon their individual toxicities(5,6). Interactions between concomitantly occurring mycotoxins can be antagonistic, additive or synergistic. Data on the combined toxic effects of mycotoxins are limited and, therefore, the actual combined health risk from exposure to mycotoxins is unknown(6). Worldwide surveys on the occurrence and contamination levels of mycotoxins in raw materials also indicate that deoxynivalenol (DON) and fumonisins (FB) are the most frequently detected mycotoxins(3,4). It was thus of interest to determine their toxic effect when present simultaneously.

The intestinal tract is the first barrier against ingested antigens, including mycotoxins and pathogenic bacteria. Following ingestion of mycotoxin-contaminated food,
enterocytes may be exposed to high concentrations of toxins(7). A role of food-associated mycotoxins in the induction or persistence of human chronic intestinal inflammatory diseases has also been suspected(8). Studies focusing on the influence of food-derived antigens on intestinal morphology as an indicator of animal health are common; however, there are few publications on the effects of chronic exposure to a mycotoxin co-contaminated diet.

FB are toxic and carcinogenic mycotoxins produced by Fusarium verticillioides and F. proliferatum, common pathogens of maize. Acute intoxication with high doses of FB (> 50 mg/kg feed) causes porcine pulmonary oedema and equine leukoencephalomalacia(9). Ingestion of lower doses (5 mg/kg feed) predisposes pigs to lung pneumonia(10). In developing countries, an association between FB and equine leukoencephalomalacia has been poorly investigated. Ingestion of higher doses (5 mg/kg feed) predisposes pigs to lung pneumonia(11). In vitro, ingestion of FB induces villous fusion and atrophy, affecting the intestinal absorption of nutrients. Also, it has been shown that 8–10 mg fumonisin/kg feed alters the cytokine profile and decreases the specific antibody response(15,16). In vivo, the ability to produce cytokines in cell lines(12–14) has been demonstrated(24). The diet formulations and nutrient contents described(24) were shown to increase the permeability of the epithelium and enterocytes may be exposed to high concentrations of toxins(7).

DON causes toxic and immunotoxic effects in a variety of cell systems and animal species(17). DON is produced by F. graminearum and F. culmorum mainly in wheat, barley and maize. Swine are more sensitive to DON than other species, in part because of differences in the metabolism of DON. Chronic low dietary concentrations (0.05–2.5 mg/kg feed) induce anorexia, decreased weight gain and immune alterations, while acute higher doses induce vomiting, haemorrhagic diarrhoea and circulatory shock(17–19). At the cellular level, the main effect is the inhibition of protein synthesis via DON binding to the ribosomes. Low exposure to DON was shown to up-regulate the expression of cytokines and inflammatory genes with concurrent immune stimulation, whereas high exposure promoted leucocyte apoptosis associated with immune suppression(17,20). At the intestinal level, 10–100 μM DON were shown to increase the permeability of the epithelium and to induce changes in the expression of claudins, a major component of the tight junctions in in vivo and in vitro models(21–23).

The purpose of the present study was to compare the effects of the low doses of DON and FB when fed to pigs individually and in combination, with particular emphasis on their effects on the intestine. The experimental design was a factorial assay including control feed and feed contaminated with 3 and 6 mg/kg of DON and FB individually and in combination, respectively. These contamination levels correspond to levels (1) that frequently occur naturally in cereals and (2) that only induce minimal alteration of zootecchnical parameters. We investigated the effect of DON and FB on intestine morphology, on the expression of junction proteins, as well as on the intestinal expression of cytokines.

### Materials and methods

**Animals and diets**

A total of twenty-four crossbred castrated male piglets (10.2 (SEM 1.89) kg body weight) were used in the present study. Piglets were acclimatised for 1 week in the animal facility of the INRA ToxAlim Laboratory (Toulouse, France) before being used in experimental protocols. Animals were kept in batch pens for 35 d. Feed and water were provided ad libitum throughout the experimental period. The animals were subjected to one of four dietary treatments for 35 d: control diet (0.5 mg DON/kg feed, FB below the limit of detection); diet containing 2.8 mg DON/kg feed; diet containing 5.9 mg FB/kg feed (+1 mg FB1 and +1.8 mg FB2); diet containing 3.1 mg DON and 6.5 mg FB/kg feed (+4.5 mg FB1 and +2.1 mg FB2). The diets were artificially contaminated with the fungal culture material containing DON and FB, as already described(24). The diet formulations and nutrient contents are described in Table 1. Even if the feed intake of the animals was not measured in the experiment, we can estimate that piglets were exposed to 130 and 260 μg/kg body weight per d of DON and FB, respectively.

Deoxyribonucleic acid, zearealenone and enniatin were found to be naturally present in the cereals used, resulting in the concentrations of 500, 50 and 100 μg/kg feed, respectively. All other mycotoxins, including fumonisin, aflatoxins, T-2 toxin, HT-2 toxin and ochratoxin A, were below the limit of detection.

The experimental design used in the present study was entirely randomised with six replicates (each animal representing one replicate). At the end of the experiment, pigs were fasted overnight before being subjected to electrical stunning and euthanised by exsanguination. Samples from

the mid-jejunum and proximal ileum were collected from each animal from all groups and fixed in 10% buffered formalin solution for histological analysis. In addition, samples from the same regions of the intestine were collected, flash-frozen in liquid N₂ and stored at −80°C until processed for measurements of junction proteins and cytokine mRNA. The institutional Ethics Committee for Animal Experimentation approved the study.

Histological assessment of the intestine

The tissue pieces fixed in 10% buffered formalin were dehydrated through graded alcohols and embedded in paraffin wax. Sections (3 μm) were stained with haematoxylin–eosin for histopathological evaluation. A lesional score was designed to compare histological changes. The frequency and severity of each lesion were considered in the score, as already described.25 The following criteria were included in the score: morphology of villi; morphology of enterocytes; interstitial oedema; lymph vessel dilation (Table 2). The lesion score was calculated by taking into account the degree of severity (severity factor) and the extent of each lesion (according to intensity or observed frequency, scored from 0 to 3). For each lesion, the score of the extent was multiplied by the severity factor.

To evaluate goblet cell density, sections of the intestine were stained with alcian blue. Positively stained goblet cells were counted randomly in five fields per sample at 40× magnification, and the means were subjected to statistical analysis.

Villi height and crypt depth were measured randomly on thirty villi using a MOTIC Image Plus 2.0 ML® image analysis system (MOTIC Image Plus Motic Instruments, Richmond, Canada). The number of lymphocytes, plasma cells and eosinophils was counted randomly based on morphometry on three fields per sample at 40× magnification. The number of mitotic figures in the enterocytes was counted in twenty fields per slide using 40× magnification. Each field corresponds to a surface area of 1.5 mm². The means of lesional score, intestinal morphometry, number of goblet cells, inflammatory infiltrate and mitosis were utilised for statistical analysis.

Immunohistochemical assessment of the expression of junction molecules

E-cadherin expression was analysed on formalin-fixed, paraffin-embedded intestinal sections to evaluate intestinal-cell adherens junctions. Tissue sections were deparaffinised with xylene and dehydrated through a graded ethanol series. Heat-mediated antigen retrieval was done by heating the sections (immersed in EDTA buffer, pH 9-0) in a microwave oven (750 W) for 15 min. Endogenous peroxidase activity was blocked by incubation in methanol–H₂O₂ solution. The sections were incubated overnight at 4°C with the primary antibody (diluted 1:50, anti-E-cadherin Clone 4A2C7; Zymed, San Francisco, CA, USA) suitable for the detection of E-cadherin by immunohistochemistry. The secondary antibody (Kit Super Picture™; Zymed, South San Francisco, CA, USA) was applied followed by the addition of a chromogen (3,3′-diaminobenzidine). Finally, the tissue sections were counterstained with haematoxylin and mounted on coverslips using a permanent mounting medium. Tissue sections were examined, and the proportion of the intestinal section expressing E-cadherin was estimated. Each sample was assessed as showing either normal or reduced staining. Normal staining was considered when homogeneous and strong basolateral membrane staining of the enterocytes was detected. Heterogeneous and weak staining was considered to indicate reduced expression. The results are reported as the percentage of animals showing strong/homogeneous immunoreactivity to E-cadherin.

Western blot analysis of junction proteins

Proteins were extracted from the ileum and assayed as described previously.26 Briefly, the extraction was carried out on ice in extraction buffer. The protease inhibitor cocktail (antipain, pepstatin, benzamidine, aminothyl benznesulfol-nyl hydrochloride, aprotinin and leupeptin) was added to the extraction buffer just before use. Extracts of tissue proteins were then separated by SDS-PAGE. Equal amounts of proteins were loaded on a 12.5% acrylamide gel. Migration was conducted in 250 mm-Tris buffer (pH 7.6) containing 1% SDS and 1.92 M-glycine. After separation, proteins were transferred onto an Optitran BA-S 83 membrane (Whatman®, Dassel, Germany). In previous studies,22,26 we have observed that DON decreases the expression of claudins. In the present study, we extended our knowledge concerning the effect of mycotoxins on junction proteins and evaluated the effect of DON and FB on another tight junction protein (occludin) and on an adherens junction protein (E-cadherin). The antibodies used in the present study were E-cadherin (24E10) rabbit mAb (diluted 1:500; Cell Signaling Technology, Danvers, MA, USA), rabbit anti-occludin (672381A, diluted 1:500; Invitrogen, Cergy-Pontoise, France) and β-actin mouse mAb (8H10D10; Cell Signaling). These antibodies are suitable for the detection of proteins by Western blot. Expression of β-actin was used for checking the equal protein

* The score for each lesion was obtained by multiplying the severity factor (or degree of severity) with the extent of the lesion. The organ score was then obtained by the sum of each lesion score. Severity factor (or degree of severity) was determined as: 1, mild lesions; 2, moderate lesions. The extent of each lesion (intensity or observed frequency) was evaluated in three slides per animal and scored as: 0, no lesion; 1, low extent (25% of the intestinal section affected); 2, intermediate extent (50% of the intestinal section affected); 3, large extent (75% of the intestinal section affected). Each intestinal section was 1 cm².
load across gel tracks. Band densities were obtained by scanning the membranes using the Odyssey® Infrared Imaging System (LI-COR; ScienceTec, Les Ulis, France). Density data were standardised within membranes by expressing the density of each band of interest relative to that of β-actin in the same lane.

**Determination of the expression of mRNA encoding for cytokines by real-time PCR**

Tissue RNA was processed in lysis matrix D tubes (MP Biomedicals, Illkirch, France) containing guanidine thiocyanate–acid phenol (Extract-All®; Eurobio, Les Ulis, France) for use with the FastPrep-24 (MP Biomedicals, Illkirch, France). Concentration, integrity and quality of RNA were determined spectrophotometrically (optical density at 260 nm) using Nanodrop ND1000 (Llabtech International, Paris, France). In addition to this assessment, 200 ng RNA were reverse transcribed using M-MLV RT (Rnasin® plus; Promega, Charbonnière, France) and random primers (5 min at 37°C, 1 h at 42°C, 15 min at 70°C; Invitrogen), as already described(27). Real-time PCR assays were performed on 8 ng cDNA (RNA equivalent) in a 25 μl reaction per well using the Power SYBR® Green PCR Master Mix as the reporter dye and the automated photometric detector ABI Prism 7000 Sequence Detection System for data acquisition (Applied Biosystems, Courtaboeuf, France). The amplification conditions were as follows: 95°C for 10 min followed by forty cycles of 95°C for 15 s and 60°C for 1 min. RNA non-reverse transcript was used as a non-template control to verify that no genomic DNA amplification signal existed. Specificity of transcript was used as a non-template control to verify that the DON-treated group, 9.52 (SEM 0.37) and 31.12 (SEM 1.75) kg for the control group, 10.46 (SEM 1.24) and 28.98 (SEM 1.75) kg for the DON-treated group, 9.54 (SEM 0.99) and 30.50 (SEM 1.34) kg for the FB-treated group and 10.16 (SEM 0.42) and 28.05 (SEM 1.42) kg for the FB control group, were evaluated using Fisher’s test.

**Results**

**Individual or combined effects of deoxynivalenol and fumonisins on the histology and morphometry of the intestine**

Ingestion of the diet contaminated with DON and FB, alone or in interaction, did not significantly modulate animal weight. The initial and final body weights of animals in the different groups were 9.54 (SEM 0.99) and 30.50 (SEM 1.34) kg for the control group, 10.46 (SEM 1.24) and 28.98 (SEM 1.75) kg for the DON-treated group, 9.52 (SEM 0.37) and 31.12 (SEM 1.63) kg for the FB-treated group and 10.16 (SEM 0.42) and 31.08 (SEM 1.42) kg for the FB control group, respectively.

RPL32, ribosomal protein L32; F, forward; R, reverse; MIP-1β, macrophage inflammatory protein-1β.
28·92 (SEM 1·91) kg for the DON + FB-treated group (NS). In addition, no overall sign of toxicity was observed in animals from the different groups.

Samples of the jejunum and ileum were collected for histomorphometrical analysis. Piglets fed the diets contaminated with mycotoxins showed mild to moderate intestinal lesions. The main histological changes observed were multifocal atrophy and villi fusion, apical necrosis of villi, cytoplasmatic vacuolation of enterocytes and oedema of lamina propria. Lymphatic vessel dilation and prominent lymphoid follicles were also observed. As indicated by the lesional scores, piglets fed mycotoxin-contaminated diets (DON, FB or DON + FB) displayed significant jejunal and ileal lesions when compared with animals fed the control diet (Fig. 1).

Changes in villous height reflect changes in the balance between epithelial cell proliferation and apoptosis. As shown in Fig. 2, villi height decreased significantly in the jejunum of the animals that received DON- or DON + FB-contaminated diet when compared with the control piglets. No change in crypt depth was observed in any intestinal region. Goblet cells synthesise and secrete mucin, which is involved in gut barrier function. The number of goblet cells decreased significantly in the jejunum and the ileum of piglets fed DON- or FB + DON-contaminated diet, respectively (Fig. 3).

Increased numbers of lymphocytes, plasma cells and eosinophils were observed in all regions of the intestine. In the groups receiving a mycotoxin-contaminated diet, a reduction in lymphocytic infiltration was observed in both regions of the intestine. However, this decrease was only significant in the jejunum of DON-treated animals and in the ileum of DON + FB-treated piglets (Fig. 3). By contrast, the number of plasma cells and eosinophils in the lamina propria increased significantly in the jejunum of animals fed the FB-contaminated diet.

**Individual or combined effects of deoxynivalenol and fumonisins on intestinal cell proliferation**

Epithelial cell proliferation was estimated by counting the number of mitosis figures in the enterocytes on haematoxylin–eosin-stained slides. The mean number of mitosis per microscopic field in the jejunum was 2·36 (SEM 1·64) in the control group, 1·73 (SEM 1·35) in the DON-treated group, 1·08 (SEM 0·86) in the FB-treated group, and 1·23 (SEM 1·26) in the DON + FB-treated group (NS). As shown in Fig. 2, villi height decreased significantly in the jejunum of the animals that received DON- or DON + FB-contaminated diet when compared with the control piglets. No change in crypt depth was observed in any intestinal region. Goblet cells synthesise and secrete mucin, which is involved in gut barrier function. The number of goblet cells decreased significantly in the jejunum and the ileum of piglets fed DON- or FB + DON-contaminated diet, respectively (Fig. 3). By contrast, the number of plasma cells and eosinophils in the lamina propria increased significantly in the jejunum of animals fed the FB-contaminated diet.
1.66 (SEM 1.11) in the FB-treated group and 1.91 (SEM 1.19) in the DON + FB-treated group. In the ileum, the mean number of mitosis per microscopic field (1.5 mm²) was 1.75 (SEM 1.26), 1.78 (SEM 1.46), 1.62 (SEM 1.17) and 1.89 (SEM 1.11) for the control group, DON-treated group, FB-treated group and DON + FB-treated group, respectively. A significant decrease \((P, 0.05)\) was observed in the jejunum of the groups fed mono-contaminated diets compared with the control group.

**Individual or combined effects of deoxynivalenol and fumonisins on intestinal immune response**

To evaluate the mechanisms of porcine intestinal defence against mycotoxin exposure, we quantified the expression of genes coding for pro-inflammatory cytokines. Table 4 describes the expression of nine cytokines (IFN-\(\gamma\), IL-1\(\beta\), IL-2, IL-6, IL-8, IL-10, IL-12p40, MIP-1\(\beta\) and TNF-\(\alpha\)) in the jejunum and the ileum of piglets exposed to DON and FB alone or in combination.

Despite an important variability, all the cytokines assessed showed a tendency and/or significant increase of their expression in intestinal samples from piglets receiving mycotoxin-contaminated diets. However, expression of cytokines revealed different profiles according to treatments and intestinal region. DON induced a significant induction of the expression of IL-1\(\beta\), IL-2, IL-6, IL-12p40 and MIP-1\(\beta\) in the jejunum, and a significant induction of the expression of TNF-\(\alpha\), IL-1\(\beta\) and IL-6 in the ileum. By contrast, ingestion of FB-contaminated feed had only a moderate effect on the expression of cytokines. It included a significant expression of IL-10 and IFN-\(\gamma\) in the jejunum and the expression of TNF-\(\alpha\) and IL-1\(\beta\) in the ileum. When animals were given the DON + FB co-contaminated diet, the expression of TNF-\(\alpha\) and IL-1\(\beta\) in their ileum and the expression of IL-10, IFN-\(\gamma\), IL-1\(\beta\), MIP-1\(\beta\), IL-2 and IL-12p40 in their jejunum were not different from the one observed in the intestine of animals fed the mono-contaminated diet. Of note, the expression of IL-6 was only up-regulated after ingestion of the DON-contaminated diet (+117% in the jejunum and +113% in the ileum when compared with animals receiving the control feed).

**Individual or combined effects of deoxynivalenol and fumonisins on the intestinal expression of junction proteins**

The adherence of the enterocytes and the permeability of the intestinal epithelium are formed to a large extent by multi-protein junction complexes. The expression of two junction proteins, E-cadherin and occludin, was analysed in the ileum of animals by Western blotting. After normalisation by the housekeeping protein \(\beta\)-actin, the data revealed a significant decrease in the expression of both proteins in animals receiving mycotoxin-contaminated diets compared with those receiving a control diet (Fig. 4).

As Western blot indicated a significant decrease in the total amount of E-cadherin expression in the ileum, we decided to evaluate the expression of this protein in the enterocytes,
using an immunohistochemical assay. The expression of E-cadherin in the jejunum and ileum was significantly reduced in the groups that received the mono-contaminated or co-contaminated diets (Fig. 5).

Discussion

Co-contamination of grains and feed has been frequently reported worldwide and the occurrence of single-mycotoxin contamination seems to be rare\(^3,20\). However, most studies investigating the toxic effect of mycotoxins have been performed with feed spiked with a single mycotoxin at high dose. It was thus of interest to determine the effect of the ingestion of feed contaminated with more than one mycotoxin on the intestine. The intestine is the first barrier against mycotoxins and could be exposed to high doses of these toxins\(^7\).

In the present study, we have investigated the effect of FB and DON on the intestine of piglets in order to determine whether they have additive, synergistic or antagonistic effects. FB and DON act through different mechanisms on the intestinal epithelium against adhesion and invasion by pathogens\(^17,20\). Villi flattening in the jejunum is probably due to the impairment of cell proliferation, as could be observed by the decrease in the number of mitotic figures in the same region.

The number of goblet cells in the intestinal wall reflects the intestinal potential of mucin production. The large protein synthesis load of these secretory cells renders them susceptible to endoplasmic reticulum stress\(^33\). Considering that the decrease in goblet cell density was not related to villi flattening (data not shown), we can hypothesise that DON in mucus-producing cell lines induces endoplasmic reticulum stress, leading to changes in intestinal cell density. Hyperplasia of intestinal goblet cells has been observed in piglets and broiler chicks receiving feed contaminated with 30 and 300 mg FB/kg feed, respectively\(^34,55\). In the present study, a decrease in the number of goblet cells was observed in piglets fed the DON-contaminated and the DON + FB co-contaminated diets, while in animals receiving the FB-contaminated diet, no effect was observed. The difference in the effect of FB on goblet cells could be due to the low dose of FB used in the present experiment. Intestinal mucus protects the epithelium against adhesion and invasion by pathogens\(^30\), therefore, a reduction in the number of goblet cells can affect the intestinal barrier function. The mechanisms involved in the alterations on the production and composition of the intestinal mucus layer by mycotoxins are still unknown and further studies are required.

\(^a,b\) Mean values with unlike superscript letters were significantly different for each cytokine (P<0.05).
Mycotoxins induce intestinal changes in pigs

Controversial results have been reported with respect to intestinal proliferation in in vitro and in vivo studies during mycotoxicosis. In the present study, we evaluated cell proliferation by counting mitotic figures in intestinal crypts, and we observed a significant decrease in proliferating cells in the jejunum of the FB- and DON-treated groups. Other studies have demonstrated that subchronic exposure to FB or DON and other mycotoxins increases the number of mitotic figures. This difference could be due to the animal model used as well as the dose and duration of the experiment. Despite very different modes of action, both DON and FB have been found to decrease the proliferation of intestinal epithelial cells. Indeed, Bouhet et al. observed a decrease in the proliferation of porcine intestinal epithelial cells treated with FB in vitro due to a blockade in the G0/G1 cell-cycle phase. Similarly, van de Walle et al. detected an in vitro decrease in the proliferation, associated with an inhibition of protein synthesis, of human intestinal epithelial cells treated with DON.

Mononuclear and eosinophil inflammatory infiltrate has been reported during FB mycotoxicosis in several animal species. In addition, proliferation of lymphoid nodules in the ileum and caecum has also been observed. We have shown that DON and DON + FB induced a significant decrease in the number of lymphocytes in the jejenum and ileum, whereas FB induced a significant increase in eosinophils and plasma cells in the jejunum. Lymphocyte depletion of lymph nodes and spleen has been reported in young pigs fed a diet contaminated with DON and zearalenone. Studies of macrophages and lymphocytes have shown that the trichothecene-mediated immunosuppressive effect was associated with the induction of apoptosis by the activation of c-Jun terminal kinase, p38 mitogen-activated protein kinase and caspases. Because lymphoid cells are constantly renewing, lymphocytes could be particularly sensitive to DON. On the other hand, DON stimulates the production of mucosal antibodies by plasma cells through the up-regulation of pro-inflammatory cytokines.

In the present study, exposure of piglets to the chronic doses of FB, DON or both in the feed induced the activation of the pro-inflammatory cytokine network in the intestine. As already described in rodents, we have observed that DON specifically induced the expression of IL-6. This can be related to the specific effect of DON on IgA synthesis that has been observed on DON-treated animals. A pro-inflammatory effect has also been observed in human enterocytes exposed to DON, as demonstrated by an increased expression of IL-8. It has been established that the intestine has its own immune network, which can cause localized induction of various cytokines and chemokines. Increases in intestinal cytokine mRNA profile indicative of macrophage and TH1 activation have been reported after DON and FB exposure. TNF-α and IL-1β are known to induce apoptosis via the receptor–ligand-mediated mechanism. We hypothesise that, besides the known apoptotic mechanisms, FB and DON could induce TNF-mediated lymphocyte and epithelial apoptosis in the intestine, which could explain the decrease in the number of these cells observed in exposed pigs. A relationship between clinically relevant concentrations of TNF-α and IL-1β and an increase in intestinal tight junction permeability has been demonstrated in Caco-2 cells. With regard to this association, we can consider that the increased levels of TNF-α and IL-1β observed after the ingestion of DON and FB in the ileum could also contribute to tight-junction ileal barrier defects.

In previous studies, we have observed that DON decreases the expression of claudins. In the present study, we observed that other junction proteins, such as occludin and E-cadherin, were also affected by exposure to mycotoxins. To the best of our knowledge, this is the first study reporting a reduced expression of E-cadherin in the intestinal tract after ingestion of a mycotoxin-contaminated diet. The reduction of E-cadherin and occludin suggests a loss of enterocytes’ adhesive properties that would correlate with an increased intestinal translocation of toxic luminal antigens, promoting intestinal inflammation, with an abnormal delivery of antigens via a paracellular pathway, and with an increased susceptibility to enteric infections.
the toxins can be classified in four different categories: syner-
gistic, additive, less-than-additive or antagonistic effects\(^{(6)}\). In
the present study, we observed synergistic interactions in the
number of goblet cells and eosinophils in the ileum, additive
interactions in the expression of IL-10, TNF-\(\alpha\) and adherent
proteins, less-than-additive interactions in the expression of
IFN-\(\gamma\) and in lesion scores, and antagonistic interactions for
some cell populations (goblet cells, plasma cells, eosinophils
and lymphocytes in the jejunum) and some cytokine
expression (IL-1\(\beta\) and IL-6). It is commonly assumed that
mycotoxins with the same mode of action and/or with the
same cellular target would have a synergistic or additive
effect when present together\(^{(50)}\). DON and FB specifically
target activated or renewing cells, thus they may affect intesti-
nal cells (lymphocytes, goblet cells or enterocytes). At the
molecular level, exposure to either DON or FB quickly results
in the activation of mitogen-associated protein kinase\(^{(20,26,51)}\)
that are known to modulate numerous physiological pro-
cesses, such as cell growth, apoptosis or immune response\(^{(52)}\).
This might explain the synergistic and additive interaction that
we observed at the intestinal level. The effect in the mitogen-
associated protein kinase network cannot explain the other
interactions that we observed and we do not have a simple
hypothesis to propose. Indeed, many different factors may
influence the outcome of an interaction, such as the endpoint
assessed, the doses and the species used, or the time and
route of exposure.

When the same animals as the ones used in the present
study were analysed for their blood neutrophil counts, their
lymphocyte proliferation or their kidney lesion, a less-than-
additive interaction was observed\(^{(24)}\). An additive effect of
the toxins has been determined for the liver and the
lung lesions, the synthesis of specific antibody and the expres-
sion of cytokines in the spleen\(^{(24)}\). In the present study,
we observed that FB was able to prevent the DON-induced
intestinal expression of IL-6. The same antagonistic interaction
between these mycotoxins has already been detected for the
serum level of IgA\(^{(24)}\). Considering that IL-6 is driving the
synthesis of IgA\(^{(53)}\), it is more than likely that the ability of FB to prevent the DON-induced expression of IgA is due
to its effect on IL-6 synthesis.

Multi-contamination with low doses of mycotoxins is more
likely to occur in naturally contaminated cereals, but only a
few studies have investigated the effects of co-contaminated
mycotoxin diets in pigs\(^{(53)}\). Taken together, the present data
provide strong evidence that chronic ingestion of low
doses of mycotoxins induces tissue lesions, modulates the
immune cell count as well as the cytokine synthesis,
and decreases the expression of proteins involved in cell
adhesion. This suggests that ingestion of feed contaminated
with these toxins may predispose animals to infections by
enteric pathogens through an alteration of intestinal barrier
function.

Fig. 5. Effect of individual and combined deoxynivalenol (DON) and fumonisins (FB) exposure on the intestinal expression of E-cadherin. Pigs received a control
diet (\(\bullet\)), or a diet contaminated with DON (\(\mathbb{Q}\)), FB (\(\mathbb{Q}\)), or both DON and FB (\(\mathbb{Q}\)). (A) Jejunum of a control piglet showing a strong and (B) homogeneous immunor-
eactivity to E-cadherin. Immunoperoxidase, 20\(\times\). (C) Percentage of animals showing strong immunoreactivity to E-cadherin. \(a,b\) Mean values with unlike letters
were significantly different (\(P<0.05\)).
