Abstract. We present the Catalogue of High REsolution Spectra of Obscured Sources (CHRESOS) from the XMM-Newton Science Archive. It comprises soft X-ray emission-lines from C to Si and the Fe 3C and Fe 3G L-shell transitions. Here, we concentrate on the oxygen emission-lines O VII(f) and O VIII Ly\textalpha to shed light onto the physical processes with which their formation can be related to: active galactic nucleus vs. star-forming regions. We are analysing the relationships between the oxygen lines and the luminosities of: [OIII]\textlambda 5007, [OIV]25.89\textmu m, MIR-12\textmu m, FIR-60\textmu m, FIR-100\textmu m, and hard X-rays continuum bands.

Keywords. line: formation, plasmas, galaxies: active, galaxies: Seyfert

1. The data and the astrophysical question

The Catalogue of High REsolution Spectra of Obscured Sources (CHRESOS) arises from RGS (Reflection Grating Spectrometer onboard XMM-Newton; den Herder et al. 2001) data of 62 nearby ($z < 0.07$), Seyfert-type active galactic nuclei (AGNs). The data were obtained from the XMM-Newton Science Archive (XSA). CHRESOS gathers for the first time the soft X-ray emission-line luminosities of H-like and He-like transitions from C to Si, and the Fe 3C and Fe 3G L-shell transitions. We focus our analysis on two important oxygen emission-lines: O VII(f) (0.561 keV) and O VIII Ly\textalpha (0.654 keV). We are currently analysing them with multiwavelength (MW) nuclear data: Continuum Fluxes in 14-195 keV, 2-10 keV, Mid-Infrared (MIR)-12\textmu m, Far Infrared (FIR)-60\textmu m, and FIR-100\textmu m continua, and fluxes of two other important oxygen lines: [OIII]\textlambda 5007, and [OIV]25.89\textmu m in the IR. Since we are probing into the formation mechanism of O VII(f) and O VIII Ly\textalpha, the MW data were chosen because of their known relationships with the two scenarios from where these emission-lines can emerge: the AGN and the (nuclear/near nuclear) star-forming regions, or starbursts (SB).

We show some preliminary results in Figure 1. The two diagrams represent the luminosity of O VII(f) and O VIII Ly\textalpha against that of [OIII]\textlambda 5007 and FIR-100\textmu m, respectively. The former as a proxy of the AGN ionizing power in the Narrow-Line Region (NLR; e.g. Bassani et al. 1999; Schmitt et al. 2003; Heckman et al. 2005; LaMassa et al. 2010;
The excitation mechanisms of X-ray oxygen emission-lines

Figure 1. Left: diagram of O VII(f) luminosity vs. [OIII]λ5007 (NLR, AGN ionizing power). Right: luminosity of O VIII Lyα vs. FIR-100μm continuum (star formation indicator). Seyfert 1-1.2 sources are plotted as empty (red) circles; Seyfert 1.5-1.9 as (blue) asterisks, and Seyfert 2 as filled (black) squares; unclassified sources were drawn as empty (orange) diamonds.

Zhang & Feng 2017), and the latter as that of star-forming regions (Rodriguez-Espinosa et al. 1986, 1987; Mouri & Taniguchi 1992; Hatziminaoglou et al. 2010). The sources are described in Fig 1. The continuous line in each diagram represents the best linear fitting (in log space). The data of [OIII]λ5007 were collected from Schmitt et al. (2003); Heckman et al. (2005) and Panessa et al. (2006); and that from FIR-100μm continuum was obtained from Sanders et al. (1989, IRAS).

So far, we have found that O VII(f) and O VIII Lyα luminosities are strongly related to [OIII]λ5007, [OIV]25.89μm, MIR-12μm, and the two primary continuum X-ray bands. However, the relationships that point to an origin from the star-forming regions are also meaningful. The two relationships shown in Fig. 1 are statistically significant (90% confidence level) in spite of the small sample size in each diagram (28 and 17 data points, respectively). We continue analysing these relationships and their statistical significance, in order to disentangle the main ionizing mechanisms taking place in the soft X-ray emitting gas.
