**Abstract**

Haemogregarines (Apicomplexa: Adeleorina) are a diverse group of haemoparasites reported from almost all vertebrate classes. The most commonly recorded haemogregarines to parasitise anurans are species of *Hepatozoon* Miller, 1908. To date 16 *Hepatozoon* species have been described from anurans in Africa, with only a single species, *Hepatozoon hyperoli* (Hoare, 1932), infecting the member of the Hepatozoidae. Furthermore, only two *Hepatozoon* species are known from South African anurans, namely *Hepatozoon tenuis* (Netherlands, Cook and Smit, 2014, from *Amietia delalandi* (syn. *Amietia quecketti*) and three *Sclerophrys* species, respectively. Blood samples were collected from a total of 225 individuals representing nine hyperoliid species from several localities throughout northern KwaZulu-Natal, South Africa. Twenty frogs from three species were found positive for haemogregarines, namely *Afrixalus fornasinii* (6/14), *Hypelorus argus* (2/39), and *Hypelorus mammoratus* (12/74). Based on morphological characteristics, morphometrics and molecular findings three new haemogregarine species, *Hepatozoon involucrum* Netherlands, Cook and Smit, *Hepatozoon quecketti* Netherlands, Cook and Smit and *Hepatozoon thorni* Netherlands, Cook and Smit, are described from hyperoliid hosts. Furthermore, molecular analyses show anuran *Hepatozoon* species to be a separate monophyletic group, with species isolated from African hosts forming a monophyletic clade within this cluster.

**Introduction**

Haemogregarines (Apicomplexa: Adeleorina) are heteroxenous, intraerythrocystic or intraeleucytic parasites, infecting a broad range of vertebrate intermediate hosts including amphibians, reptiles, fishes, birds and mammals. These parasites are possibly transmitted by an equal diversity of haematophagous invertebrate definitive hosts or vectors, such as dipteran insects, ticks, mites, leeches and even gnathiid isopods (see Smith, 1996; Davies and Johnston, 2000; Curtis et al. 2013). Haemogregarines are currently divided into four families (Barta et al. 2012), namely Dactylosomatidae Jakowska and Nigrelli, 1955, Haemogregarinidae Léger, 1911, Hepatozoidae Miller, 1908, and Karyolysidae Labbé, 1894.

Within the Hepatozoidae, *Hepatozoon* Miller, 1908 is characterized by the presence of gamonts in erythrocytes or leucocytes, with no merogonic division occurring in the peripheral blood of the vertebrate host. Furthermore, *Hepatozoon* species are characterized by the pairing (syzygy) of gamonts in the definitive invertebrate host or vector following a blood meal. These paired gamonts then penetrate the gut wall and enter the haemocoel where sporogonic development and ultimately the formation of large oocysts occur. These thick-walled oocysts (also known as large multisporocystic oocysts) contain sporocysts with sporozoites, the infective stages of the parasite, which emerge upon the ingestion by the intermediate vertebrate host and give rise to merogonic stages in the liver (Desser et al. 1995; Smith, 1996; Barta, 2000).

*Hepatozoon* species are the most commonly reported haemogregarines to parasitize anurans. Currently, there are 45 recognized species from anurans globally, with 16 of these
described from African hosts (see Smith, 1996; Netherlands et al. 2014a, b). According to Netherlands et al. (2014a), the majority of these species (12/16) were described from the Bufonidae, namely Hepatozoon aegyptia (Mohammed and Mansour, 1963), Hepatozoon assiaticus (Abdel-Rahman, El-Naffar, Sakla and Khalifa, 1978), Hepatozoon boueti (França, 1925), Hepatozoon faiyumensis (Mansour and Mohammed, 1966), Hepatozoon franci (Abdel-Rahman, El-Naffar, Sakla and Khalifa, 1978), Hepatozoon froilanoi (França, 1925), Hepatozoon ixoo Netherlands, Cook and Smit, 2014, Hepatozoon lavieri (Tuzet and Grjebine, 1957), Hepatozoon magni (Hassan, 1992), Hepatozoon moloensis (Hoare, 1920), Hepatozoon pestanae (França, 1910), and Hepatozoon tunisiensis (Nicolle, 1904). Two species were described from the Pyxicephalidae, namely Hepatozoon epiusensis (Van den Bergh, 1942), and Hepatozoon neireti (Laveran, 1905), and only a single species from the Pyxicephalidae and Hyperoliidae, namely Hepatozoon theileri (Laveran, 1905), and Hepatozoon hyperolli (Hoare, 1932), respectively. Apart from Hepatozoon hyperolli, which was described from an unidentified Hyperolius species in Uganda (Hoare, 1932), the only other Hepatozoon species reported from the Hyperoliidae are two unnamed species reported in Hyperolius marmoratus and Hyperolius puncticulatus, from northern KwaZulu-Natal (KZN), South Africa (Netherlands, Cook and Smit, 2014) and Amani, Tanzania (Ball, 1967), respectively. In South Africa, only two Hepatozoon species are known from anurans, namely H. theileri and H. ixoo, from the pyxicephalid Amietia delalandii (syn. Amietia queuecri) and three Sclerophrys species (Bufonidae) respectively, namely Sclerophrys pusilla (syn. Ameiophrynus maculatus), Sclerophrys (syn. Amietophrynus) garmani and Sclerophrys (syn. Amietophrynus) gutturalis.

Over the past decade several phylogenetic studies on adeleorinid parasites, using 18S rDNA sequences, have provided useful insight into the evolutionary relationships of this group, as well as the better capability to distinguish between species. However, because the 18S rRNA nuclear gene is a relatively conserved marker, it shows certain nodes to be unresolved (Barta et al. 2012; Maia et al. 2012; Haklová-Kočková et al. 2014; Cook et al. 2016). In an effort to resolve these polytomies, a new genus Bartazoon Karadjian, Chavatte and Landau 2015, was proposed for species previously regarded as belonging to Hepatozoon parasitizing reptiles, amphibians, marsupials, birds and rodents, and was proposed to be transmitted solely by biting insects (Karadjian et al. 2015). However, the suggested life history of certain species within the proposed genus such as Hepatozoon fitzi-monsi (Dias, 1953) do not conform to the recommended characteristic defining Bartazoon (see Cook et al. 2014; Karadjian et al. 2015). Also as pointed out by Maia et al. (2016b), it is possible that Hepatozoon perriciosus Miller, 1908, the type species of the genus Hepatozoon, may, in fact, form part of the newly proposed genus Bartazoon, as most other rodent haemogregarine species do. Furthermore, increased work on the phylogenetic relationships of the haemogregarines continues to identify new genetic lineages, showing that Bartazoon is not a well-supported monophyletic group (Tomé et al. 2016; Maia et al. 2016a). Thus, to revise the deeper taxonomy (family and genus level) of haemogregarines based on their phylogenetic affinities and life histories, more studies using faster-evolving markers such as mitochondrial genes (e.g. Leveille et al. 2014), elucidating life cycles, and building larger datasets are necessary. Therefore, as suggested and used by Maia et al. (2016b) we will continue to refer to species parasitizing anuran hosts as species of Hepatozoon and not Bartazoon.

Prior to the study of Netherlands et al. (2014a) all the African anuran Hepatozoon species descriptions, ranging from the early 1900s till the late 1970s, were solely based on the morphology of the peripheral blood gamont stages. Unfortunately, many of these descriptions were scantily illustrated and incomplete, with almost 60% of the species described from the same host (Sclerophrys regularis) and in more or less the same geographical area (see Netherlands et al. 2014a, b). Thus many of these species may later need to be synonymized once more advanced and standardized methods are used to characterize these haemogregarines. In South Africa only five studies on amphibian haemogregarines have been carried out (Laveran, 1905; Fantham et al. 1942; Netherlands et al. 2014a, b; Netherlands et al. 2015). From these, only a single study was a multispecies haemaparasite survey across different anuran families (Netherlands et al. 2015), and although in that study several different haemogregarines were observed in anurans, only one hyperolid species, Hyp. marmoratus (as mentioned above) contained a Hepatozoon species, which was not identified to species level.

Thus the objectives of the current study were (1) to establish which hyperolid frog species in northern KZN, South Africa, contain haemogregarines, (2) to determine the species diversity of the haemogregarine parasites observed. (3) to ascertain if any of the haemogregarines found were previously described or reported species and (4) to compare any parasites characterized in the current study with available molecular data for anuran haemogregarines in order to determine their phylogenetic relationships.

Materials and methods

Frog collection and study area

A total of 225 individuals representing nine hyperolid species, were collected from several localities throughout northern KwaZulu-Natal, South Africa (Fig. 1), following the collection methods described in Netherlands et al. (2015). Frogs were identified using Du Preez and Carruthers (2009), and identifications were confirmed by one of the authors of this guide (LDp). After processing, all specimens were released at the site of capture. This study received the relevant ethical approval from the North-West University’s AnimCare ethics committee (ethics number: NWU-00372-16-A5).

Processing of samples and light microscopy screening

Blood (>0.1 mL) was taken from each frog via cardiac or femoral venipuncture and thin blood smears prepared on clean glass slides, air-dried, fixed and stained using Giemsa-stain (FLUKA, Sigma-Aldrich, Steinheim, Germany). The remaining blood was preserved in 70% ethanol for molecular work (ratio 1 : 15). Stained blood smears were screened at 1000× and images captured and measured using the imaging software NIS Elements Ver. 4 as described by Netherlands et al. (2015). Fifty mature gamonts were measured per Hepatozoon species. Measurements comprised the parasite’s length (including recurved tail when present) and width within its parasitophorous vacuole (PV), and the parasite’s nucleus length and width. Measurements of the PV length and width, and the length from mid nucleus to both anterior and posterior end of the parasite were also taken. Parasitaemia was calculated per 100 erythrocytes, with ∼10^3 erythrocytes examined per blood smear, following previous methods (see Cook et al. 2015a).

DNA extraction, PCR amplification and phylogenetic analyses

Ethanol-preserved blood samples from parasitized frog specimens (n = 10) were used for molecular work. Two additional blood samples of A. delalandii parasitized with H. theileri and S. pusilla

Downloaded from https://www.cambridge.org/core. IP address: 54.70.40.11, on 26 Sep 2018 at 23:47:57, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms . https://doi.org/10.1017/S003118201700213X
parasitized with *H. ixoxo* from a previous study (Netherlands et al. 2014a) were added to obtain longer comparative sequences as compared with the previous study by Netherlands et al. (2014a). Genomic DNA of haemogregarine species were extracted from the blood samples using the KAPA Express Extract Kit (Kapa Biosystems, Cape Town, South Africa). Once extracted, DNA was used for polymerase chain reaction (PCR) amplification. The PCR reactions targeted two fragments of approximately 940 and 1400 nt of the 18S rRNA gene. The 18S rRNA gene sequences were amplified using a combination of two primer sets based on previous studies of haemogregarines belonging to *Karyolysus* Labbé, 1894, *Hemolivia* Petit, Landau, Baccam and Lainson, 1990 and *Hepatozoon* (see Ujvari et al. 2004; Criado-Fornelio et al. 2006; Cook et al. 2015b, 2016). The first fragment was amplified using HAM-F (5′-GCCAGTAGTCA TATGCTTGTC-3′) and HepR900 (5′-CAAATCTAAGAATTTTC ACCTCTGAC-3′) (see Ujvari et al. 2004; Criado-Fornelio et al. 2006), and the second fragment HepF300 (5′-GTTTCTGACC TATCAGCTTTGCAG-3′) and 2868 (5′-TGATCCTTCTGCGA GTTCACCTAC-3′) (see Medlin et al. 1988; Ujvari et al. 2004). Conditions for PCR were as follows: initial denaturation at 95 °C for 3 min, followed by 35 cycles, entailing a 95 °C denaturation for 30 s, annealing at 61 °C for 30 s with an end extension at 72 °C for 2 min, and following the cycles a final extension of 72 °C for 10 min. PCR reactions were performed with volumes of 25 µL, using 12·5 µL Thermo Scientific DreamTaq PCR master mix (2×) (final concentration: 2× DreamTaq buffer, 0·4 mM of each dNTP, and 4 mM MgCl2), 1·25 µL (10 µM) of each of the primer sets mentioned above, and at least 25 ng DNA. The final reaction volume was made up with PCR-grade nuclease-free water (Thermo Scientific). Reactions were undertaken in a Bio-Rad C1000 Touch™ Thermal Cycler PCR machine (Bio-Rad, Hemel Hempstead, UK). Resulting amplicons were visualized under ultraviolet light on a 1% agarose gel stained with gel red using a Bio-Rad GelDoc™ XR+ imaging system (Bio-Rad, Hemel Hempstead, UK). PCR products from each sample were sent to a commercial sequencing company (Inqaba Biotechnical Industries (Pty) Ltd, Pretoria, South Africa) for purification and sequencing in both directions. Resultant sequences were assembled, and chromatogram-based contigs were generated and trimmed using Geneious R9·1 (http://www.geneious.com, Kearse et al. 2012). Sequence and species identity was verified.
against previously published sequences using the Basic Local Alignment Search Tool (BLAST) (Altschul et al. 1990). Sequences obtained in the current study were deposited in the NCBI GenBank database under the following accession numbers [GenBank: MG041591–MG041605].

For comparison, all 18S rDNA sequences of anuran haemogregarines, longer than 1500 nt (comprising species of Hepatozoon, Helomovia, Babesiosoma and Dactylosoma) as well as Hepatozoon sipedon Smith, Dessier and Martin, 1994, [GenBank: JN181157] from the snake Nerodia sipedon sipedon, were downloaded from GenBank and aligned to the sequences generated in the current study. Hepatozoon sipedon was selected as it was shown by Barta et al. (2012) to be sister to Hepatozoon catesbiana (Stebbins, 1904) and Hepatozoon clamatae (Stebbins, 1905), at that point the only two species of Hepatozoon of frogs for which 18S rDNA sequences were available. Furthermore, H. sipedon first makes use of a frog intermediate host in which tissue development occurs before transmission to its second intermediate snake host (see Smith et al. 1994). Thus all species included in the analysis have an anuran host in their life cycle. Although there are other sequences available from a Hepatozoon species characterized from the anurans Pelophylax perezi [GenBank: KP733812] and Leptodactylus chaquensis [GenBank: JX987775], from the Azores in the North Atlantic Ocean, and Pantanal, Brazil respectively, they were not added to our analysis because these concerned shorter fragments (see Harris et al. 2013; Leal et al. 2015). Babesiosoma stableri Schmittner and McGhee, 1961 [GenBank: HQ224961] and Dactylosoma ranarum Lankester, 1871 [GenBank: HQ224957; HQ224958] were chosen as the outgroup, as they were shown by Barta et al. (2012) to belong to a sister group to our current ingroup. Sequences were aligned using the MUSCLE alignment tool (Edgar, 2004) under the default settings and implemented in Geneious R9.1. The alignment consisted of 14 sequences with a 1497 nt conserved region selected using the MUSCLE alignment tool (Edgar, 2004) under the default settings and implemented in Geneious R9.1. The alignment consisted of 14 sequences with a 1497 nt conserved region selected using the Gblocks 0.91b server (Castresana, 2000). To infer phylogenetic relationships both Bayesian inference (BI) and Maximum likelihood (ML) methods were used. The BI analysis was performed using MrBayes 3.2.2 (Huelsenbeck and Ronquist, 2001) and the ML analysis was performed using RAxML Ver. 7.2-8. (Stamatakis, 2014) both implemented from within Geneious R9.1. Prior to the analyses, a model test was performed to determine the most suitable nucleotide substitution model, according to the Akaike information criterion using jModelTest 2.1.7 (Guindon and Gascuel, 2003; Darriba et al. 2012). The model with the best AICc score was the Transitional model (Posada, 2003) with estimates of invariable sites and a discrete Gamma distribution (TVM + I + Γ). However, this model was substituted by the General Time Reversible (Tavaré, 1986) model (GTR + I + Γ) in MrBayes and in RAxM, as this was the next model available with the best AICc score. For the BI analysis, the Markov Chain Monte Carlo (MCMC) algorithm was run for 10 million generations, sampling every 100 generations, and using the default parameters. The first 25% of the trees were discarded as ‘burn-in’ with no ‘burn-in’ samples being retained. Results were visualized in Trace (implemented from within Geneious R9.1), to assess convergence and the burn-in period. For the ML analysis, nodal support was assessed using 1000 rapid bootstrap inferences. Model-corrected (TVM + I + Γ) genetic distances were calculated in PAUP version 4.0a152 (Swoford, 2002), with the assumed proportion of invariable sites = 0.598 and the gamma shape parameter = 0.775.

**Results**

A total of 225 individuals representing nine species from the family Hyperoliidae, namely Afrixalus aureus (n = 18), Afrixalus delicatus (n = 13), Afrixalus fornasinii (n = 14), Hyperolius argus (n = 39), Hyperolius marmoratus (n = 74), Hyperolius tuberlinguis (n = 38), Hyperolius pusillus (n = 14), Kassina senegalensis (n = 9), and Phylctimantis (syn. Kassina) maculatus (n = 6) were collected and screened for haemogregarines. Twenty frogs (8.9%) from three species were found positive for haemogregarines, specifically A. fornasinii (6/14), Hyp. argus (2/39), and Hyp. marmoratus (12/ 74) (see Fig. 2A–C). Based on peripheral blood stages, the haemogregarines of the current study conform to the genus Hepatozoon. Although possible meront stages were observed in the peripheral blood for one species, these were rare and no merogonic division was detected. Furthermore, these haemogregarines did not compare with the closely related genus Helomovia, as no schizogony or cyst formation in the erythrocytes of the hosts was observed.

**Species descriptions**

**Phylum:** Apicomplexa Levine, 1970  
**Class:** Conoidasida Levine, 1988  
**Order:** Eucoccidiorida Léger & Duboscq, 1910  
**Suborder:** Adeleorina Léger, 1911  
**Family:** Hepatozoidae Wenyon, 1926  
**Genus:** Hepatozoon Miller, 1908

*Hepatozoon involucrum* Netherlands, Cook and Smit n. sp.  
**Type-host:** Hyperolius marmoratus Rapp, 1842 (Anura: Hyperoliidae).  
**Vector:** Unknown.  
**Type-locality:** The specimens were collected in the Kwa Nyamazane Conservancy (KNC), KwaZulu-Natal, South Africa (27°23’35’S, 32°08’41”E).  
**Other localities:** St. Lucia on Monzi Farm, KwaZulu-Natal, South Africa (28°26’56”S 32°17’18”E).  
**Type-material:** Hapantotype, 1x blood smear from *Hyp.* marmoratus deposited in the protozoan collection of the National Museum, Bloemfontein, South Africa under accession number NMB P 467; parahapantotype, 1x blood smear from *Hyp.* marmoratus; deposited in the Protozoan Collection of the National Museum.

Museum, Bloemfontein (NMB), South Africa, under accession number NMB P 468.

Representative DNA sequences: The 18S rRNA gene sequences have been submitted to the GenBank database under the accession numbers MG041591–MG041594.

ZooBank registration: The Life Science Identifier (LSID) of the article is urn:lsid:zoobank.org:pub:F73407D7-1E08-4C3C-B066-889058B77C4C. The LSID for the new name *Hepatozoon involucrum* is urn:lsid:zoobank.org:act:A43D46E8-5C9F-4405-8907-94D7B02EAEA7.

Etymology: The species epithet is derived from the Latin word *involucrum* meaning envelope or sheath, and is based on the prominent PV encircling the gamont.

Description:
Trophozoites: rare, occurring singularly within erythrocytes, oval to rounded, measuring 12.2–12.5 (12.3 ± 0.2) μm long × 4.8–5.7 (4.2 ± 0.6) μm wide (n = 2) with finely vacuolated cytoplasm staining whitish-pink (Fig. 3A and B), note lysis of the host cell nucleus (Fig. 3B). Nucleus containing loosely arranged chromatin, staining pink, measuring 3.7–5.2 (4.0 ± 1.2) μm long × 3.2–4.9 (4.0 ± 1.2) μm wide (n = 2). Mid nucleus position measuring 5.8–7.4 (6.6 ± 1.2) μm to anterior, and 5.4–5.6 (5.5 ± 0.1) μm to posterior.

Meronts: rare, irregular in shape, often with a foamy cytoplasm, staining whitish-blue to purple (Fig. 3C and D), and measuring 9.5 μm long × 8.8 μm wide (n = 1). Nucleus containing loosely arranged chromatin, staining pink to purple, measuring 6.8 μm long × 3.7 μm wide (n = 1).

Immature gamonts: elongated with small-recurved tail, within a vaguely visible PV, cytoplasm staining whitish-purple, causing displacement of the host cell nucleus (Fig. 3E). Parasite (including recurved tail) measuring 16.4–23.0 (19.8 ± 1.8) μm long × 4.4–5.7 (5.1 ± 0.4) μm wide (n = 10), PV measuring 14.2–18.4 (15.6 ± 1.3) μm long × 5.2–9.1 (6.5 ± 1.5) μm wide (n = 10). Nucleus rounded, usually situated in the posterior half of the parasite, loosely arranged chromatin, staining purple, and measuring 3.0–7.0 (5.4 ± 1.4) μm long × 2.6–5.6 (3.8 ± 0.9) μm wide (n = 10). Mid nucleus position measuring 10.0–13.7 (11.7 ± 1.4) μm to anterior side, and 6.6–11.1 (8.6 ± 1.6) μm to posterior side (n = 10).

Mature gamonts: elongated and oval, encased in a large PV (Fig. 3F–I); often recurved at both the anterior and posterior poles, and in some cases a clear recurved tail is visible (Fig. 3G, arrowhead); infrequent extracellular or free moving gamont (Fig. 3F), as well as single erythrocytes parasitised by two gamonts (Fig. 3I); gamonts cause noticeable displacement of the host cell nucleus. Parasite (including recurved tail) measuring 18.7–25.9 (21.8 ± 1.5) μm long × 4.0–6.3 (5.1 ± 0.5) μm wide (n = 50), PV measuring 16.5–20.9 (18.3 ± 1.0) μm long × 6.3–10.8 (8.3 ± 1.1) μm wide (n = 50). Nucleus elongated or loosely arranged, usually

[17x16]. https://doi.org/10.1017/S003118201700213X

Downloaded from https://www.cambridge.org/core. IP address: 54.70.40.11, on 26 Sep 2018 at 23:47:57, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms . https://doi.org/10.1017/S003118201700213X
situated in the posterior half of the parasite, lose chromatin strands often visible, staining purely-pink, and measuring 4·8–8·9 (6·4 ± 0·9) μm long × 2·2–4·2 (3·2 ± 0·4) μm wide (n = 50). Mid nucleus position measuring 8·4–19·9 (13·8 ± 1·8) μm to anterior side, and 5·4–11·6 (8·2 ± 1·4) μm to posterior side (n = 50). Parasitaemia of all infected individuals (n = 7) in percentage (%) was 1·0–30·0 (8·0 ± 2·0).

Remarks:

Based on the morphology and morphometrics of peripheral blood stages in *Hyp. marmoratus*, *H. involucrum* n. sp. does not conform morphologically to any of the 16 currently recognized *Hepatozoon* species in African anurans. The other only named species infecting a member of the Hyperoliidae, is *H. hyperolii*, and can be distinguished from *H. involucrum* n. sp. based on the shape of the former parasite’s gamont. The gamont of *H. hyperolii* is cylindrical with rounded ends and a long recurved tail folded onto itself in the absence of a prominent PV (see Fig. 6A–C). In contrast the gamont of *H. involucrum* n. sp. has an elongated and encased gamont, which is often recurved at both the anterior and posterior poles. The mean length and width of *H. involucrum* n. sp., which includes the parasite’s PV, is 18·3 μm long × 8·3 μm wide. Although these mean length measurements do overlap with several species namely, *H. faiyumensis*, *H. francii*, *H. moloensis* and *H. neireti*, the mean width in combination with the length of these species does not conform. Overall the gamont measurements of *H. involucrum* n. sp. compare closest to those of *H. moloensis* (18·8 μm long × 7·8 μm wide), which was described from an unidentified *Sclerophrys* species in Molo, Kenya (see Hoare, 1920). However, the oval shape, recurved tail and absence of a PV in *H. moloensis* are distinctive and distinguishable from *H. involucrum* n. sp. as described above. Similarly, these distinctive characteristics of *H. involucrum* n. sp. which differentiate it from *H. moloensis*, also differentiate it from other African anuran species of *Hepatozoon*.

In South Africa a *Hepatozoon* species corresponding morphologically to *H. involucrum* n. sp. was reported from the same host and area in an anuran biodiversity blood parasite survey by Nethersol et al. (2015), however, this parasite was not formally described or named (see Nethersol et al. 2015, Fig. 2D).

Globally the species that conforms most closely to *H. involucrum* n. sp. is *Hepatozoon nucleobisecans* (Shortt, 1917) described from the Indian toad *Duttaphrynus melanostictus* (syn. Bufo melanostictus). Although the reported gamont length (18·3 μm long) of *H. nucleobisecans*, including the PV, equals the mean length of *H. involucrum* n. sp., the width (4·8 μm wide) is almost half. Furthermore, the gamont of *H. nucleobisecans* is not recurved at both the anterior and posterior poles within the PV (see Shortt, 1917).

*Hepatozoon tenuis* Netherlands, Cook and Smit n. sp.

Type-host: *Afrixalus fornasinii* (Bianconi, 1849) (Anura: Hyperoliidae).

Other hosts: *Hyperolius argus* Peters, 1854; *Hyperolius marmoratus* (Anura: Hyperoliidae).

Vector: Unknown.

Type-locality: The specimens were collected in St. Lucia on Monzi Farm, KwaZulu-Natal, South Africa (28°26′56″S 32°17′18″E).

Other localities: KwaMbonambi/Langepan, KwaZulu-Natal, South Africa (28°39′43″S 32°10′06″E).

Type-material: Hapantotype, 1× blood smear from *A. fornasinii* deposited in the protozoan collection of the National Museum, Bloemfontein, South Africa under accession number NMB P 469; parahapantotypes, 1× blood smear from *A. fornasinii*, and *Hyperolius marmoratus*; deposited in the Protozoan Collection of the National Museum, Bloemfontein (NMB), South Africa, under accession numbers NMB P 470 and NMB P 471, respectively.

*Representative DNA sequences*: The 185 rRNA gene sequences have been submitted to the GenBank database under the accession numbers MG041595–MG041599.

**ZooBank registration**: The Life Science Identifier (LSID) of the article is urn:lsid:zoobank.org:pub:F73407D7-1E08-4C3C-B066-889058877C4C. The LSID for the new name *Hepatozoon tenuis* Netherlands, Cook and Smit is urn:lsid:zoobank.org:act:AD607DB8-D43D-49C6-8139-2782306FE2F5.

*Etymology*: The species epithet is derived from the Latin word *tenuis*, which means thin or slender. This refers to the long slender shape of the gamont.

*Description*:

Mature gamonts: slender and elongated, with a pinkish-white staining cytoplasm, within a close-fitting PV visible on the concave side of the gamont (Fig. 4A–C); in some cases a recurved tail is visible (Fig. 4A and D arrowhead); also an occasional extra-cellular or free moving gamont, (Fig. 3E arrow), as well as a single erythrocyte parasitised by two gamonts (Fig. 4F); gamonts cause obvious displacement of the host cell nucleus. Parasites (including recurved tail when visible) measuring 11·2–16·8 (13·9 ± 1·6) μm long × 3·7–6·7 (4·8 ± 0·6) μm wide (n = 50), PV measuring 17·8–20·7 (19·4 ± 0·8) μm long × 5·0–7·5 (6·7 ± 0·4) μm wide (n = 50). Nucleus elongated and neatly arranged, usually situated in the posterior half of the parasite, loose chromatin staining purely-pink, and measuring 2·1–5·2 (3·9 ± 0·6) μm long × 1·6–4·9 (10·8 ± 0·9) μm wide (n = 50). Mid nucleus position measuring 4·8–9·4 (6·7 ± 1·1) μm to anterior, and 4·6–10·1 (7·2 ± 1·2) μm to posterior (n = 50). Parasitaemia of all infected individuals (n = 9) calculated in percentage (%) was 1·0–35·0 (6·0 ± 2·0), two (*Hyp. argus* and *Hyp. marmoratus*) of the nine infected individuals contained mixed infections the parasite described below.

Remarks:

*Hepatozoon tenuis* n. sp. parasitising *A. fornasinii*, *Hyp. argus* and, *Hyp. marmoratus*, can be distinguished from *H. involucrum* n. sp., based on the difference in gamont morphometrics. Morphologically, gamonts have an overall similar appearance to *H. involucrum* n. sp., however, gamonts of *H. involucrum* n. sp. measure a mean of 21·8 μm long × 5·1 μm wide (n = 50) (PV not included) and a mean of 18·3 μm long × 8·3 μm wide (n = 50) (PV included), as compared with gamonts of *H. tenuis* n. sp. measuring a mean of 13·9 μm long × 4·8 μm wide (n = 50) (PV not included) and a mean of 19·4 μm long × 6·7 μm wide (n = 50) (PV included). This slender looking parasite can be distinguished from other anuran *Hepatozoon* species based on the marginally visible PV, as well as often being recurved at both the anterior and posterior poles within the PV.

*Hepatozoon thori* Netherlands, Cook and Smit n. sp.

Type-host: *Hyperolius marmoratus* Rapp, 1842 (Anura: Hyperoliidae).

Vector: Unknown.

Type-locality: The specimens were collected in the Kwa Nyamzane Conservancy (KNC), KwaZulu-Natal, South Africa (27°23′35″S, 32°08′41″E).

Other localities: KwaMbonambi/Langepan, KwaZulu-Natal, South Africa (28°39′43″S 32°10′06″E); Amani, Tanzania.

Type-material: Hapantotype, 1× blood smear from *Hyp. marmoratus* deposited in the protozoan collection of the National Museum, Bloemfontein, South Africa under accession number NMB P 472; parahapantotype, 1× blood smear from *Hyp. marmoratus*; deposited in the Protozoan Collection of the National Museum, Bloemfontein, South Africa, under accession number NMB P 473.
Representative DNA sequences: The 18S rRNA gene sequences have been submitted to the GenBank database under the accession numbers MG041600–MG041603.

ZooBank registration: The Life Science Identifier (LSID) of the article is urn:lsid:zoobank.org:pub:F73407D7-1E08-4C3C-B066-889058B77C4C. The LSID for the new name Hepatozoon thori Netherlands, Cook and Smit is urn:lsid:zoobank.org:act:00CD84D9-D6A8-4B41-A048-DFD0DBF4B045.

Etymology: The species epithet is derived from Norse mythology according to the hammer-wielding god Thor. This is based on the hammer-like shape of the gamont.

Description:
Immature gamonts: rare, elongated without a visible PV, cytoplasm staining whitish-purple, measured 18.7 μm long by 5.5 μm wide (n = 1), causing displacement of the host cell nucleus and found parasitizing a single erythrocyte together with a mature gamont (Fig. 5A arrow). Nucleus rounded, situated in the posterior half of the parasite, loosely arranged chromatin, staining purple, and measuring 8.1 μm long × 2.7 μm wide (n = 1). Mid nucleus position measured 8.9 μm to anterior side, and 9.8 μm to posterior side (n = 1).

Mature gamonts: elongated, causing displacement of the host cell nucleus. Encased in a prominent hammer-like or boot-shaped PV, with a pseudopodial-like projection (Fig. 5A–F); occasionally a short recurved tail is visible (Fig. 5C and D arrow); mature gamonts cause the host cell nucleus to lyse (Fig. 5E); extracellular or free moving gamont, possibly probing to enter new host cell (Fig. 5F). Parasite measuring 11.2 μm long × 4.8 μm wide (PV not included) and 19.4 μm long × 6.7 μm wide (n = 50) (PV included). Based on the size and shape, the only other haemogregarine H. thori n. sp. conforms closest to is an unnamed Hepatozoon species (see Fig. 6D and E), measuring a mean of 14.1 μm long × 4.8 μm wide (PV not included) and 20.8 μm long × 6.7 μm wide (PV included). This unnamed species was reported in Hyperolius punctuculatus, from Amani, Tanzania (see Ball, 1967) (see below).

Phylogenetic analysis
Amplicons of between 1640 and 1701 nt were derived from H. involucrum n. sp., H. tenuis n. sp., and H. thori n. sp., and other anuran Hepatozoon species based on the distinctive shape of the hammer-like or boot-shaped PV that has a pseudopodial-like projection. The mean length and width of the parasite measure 13.9 μm long × 4.8 μm wide (PV not included) and 19.4 μm long × 6.7 μm wide (n = 50) (PV included). The details of sequences used in the analyses are presented in Table 1. Based on 1497 nt sequence comparisons of the 18S rRNA gene (see Table 2), the interspecific divergence (model-corrected genetic distance) between H. involucrum n. sp. and its closest relative H. tenuis n. sp. was 1.0%.

Remarks:
Hepatozoon thori n. sp. parasitizing Hyp. argus and Hyp. marmoratus can be distinguished from H. involucrum n. sp., H. tenuis n. sp., and other anuran Hepatozoon species based on the interspecific divergence of 2.0%.
divergence between the *Hepatozoon* species parasitizing anuran hosts and *Hepatozoon sipedon* [GenBank: JN181157] was between 7.7 and 10.6%. The intergeneric divergence between the *Hepatozoon* species parasitising anuran hosts, and *Hemolivia stellata* Petit, Landau, Baccam and Lainson, 1989 [GenBank: KP881349], *B. stableri* [GenBank: HQ224961] and *D. ranarum* [GenBank: HQ224957; HQ224958] were between 4.9–5.8%, 8.8–9.6% and 8.5–9.7%, respectively (Table 2).

For the phylogenetic analyses the topologies of both the BI and ML trees were similar. The analyses showed *Hemolivia stellata*

---

**Fig. 5.** *Hepatozoon thori* n. sp. gamonts parasitizing erythrocytes in the reed frogs *Hyperolius marmoratus* (A–C) and *Hyperolius argus* (D–F). (A) Double infection of a single erythrocyte, with an immature (arrow) and mature (arrowhead) gamont. (B–F) Prominent hammer-like or boot-shaped parasitophorous vacuole, allowing only a certain portion of the gamont to be visible. (C and D, arrow) Gamont displaying a short recurved tail. (E) Gamont causing the host cell nucleus to lyse. (F) Extracellular or free gamont. All images captured from the deposited slides (NMB P 472 & 473). Scale bar: 10 µm.

Discussion

In the present study, we screened the peripheral blood of 225 individual frogs from nine species within the Hyperoliidae. Six species (A. aureus, A. delicates, H. tuberlinguis, H. pusillus, K. senegalensis and P. maculatus), totalling 205 specimens were found negative for haemogregarine parasites. Only 20 frogs from three species were found positive, namely A. fornasinii (6/14), H. argus (2/39), and H. marmoratus (12/74).

Morphological and molecular data indicate that the haemogregarines parasitising these hosts represent three distinct species of Hepatozoon, herein described as *H. involucrum* n. sp. parasitising *H. marmoratus*; *H. tenuis* n. sp., parasitising *A. fornasinii, H. argus* and *H. marmoratus*; and *H. thori* n. sp. parasitising *H. argus* and *H. marmoratus*. Mature gamonts of *H. involucrum* n. sp. are characterized by the prominent PV encircling the large gamont, as well as the recurved ends of both poles of the gamont. When compared with *H. tenuis* n. sp., the overall appearance and characteristics are similar, except for a difference in size of the gamont and PV. The interspecific divergence between these two species is 1.0%. This has been shown in several studies to correspond to species-level differences in haemogregarines and for the slow evolving 18S rRNA marker (see Barta et al. 2012; Cook et al. 2015b; Borges-Nojosa et al. 2017). Hepatozoon thori n. sp. can be distinguished from both *H. involucrum* n. sp. and *H. tenuis* n. sp. based on the distinctive hammer-like shape of the gamont’s PV. The interspecific divergence between *H. thori* n. sp., *H. involucrum* n. sp. and *H. tenuis* n. sp. was 2.0% and 1.8%, respectively.

The only other named species of *Hepatozoon* infecting a member of the Hyperoliidae is *H. hyperolii* described in an unidentified *Hyperolius* species by Hoare (1932), this parasite being vermicular in shape and folding over on itself within its host erythrocyte (see Fig. 6A–C) and therefore does not conform to any of the *Hepatozoon* species of the present study. However, Ball (1967) reported a second, but unnamed species in *Hyperolius puncticulatus* from Amani, Tanzania, and this species conforms both in size and shape to *H. thori* n. sp. (see Fig. 6D and E). In the current study, we propose that these two species are the same, despite parasitizing different hosts and possibly being geographically isolated. However, to confirm this, molecular data for this species from Amani, Tanzania is required.

In our phylogenetic analysis, *Hepatozoon* species isolated from anuran hosts formed a well-supported monophyly, separate to other closely related species of *Hepatozoon*. Furthermore, the African clade formed a monophyly, with *H. thori* n. sp. separate from the other species within this clade. *Hepatozoon involucrum* n. sp. and *H. tenuis* n. sp. form a well-supported monophyletic clade nested within the larger African clade. With an interspecific divergence of 1.0% (model-corrected distance), these two species are closely related, which concurs with their close morphological resemblance. *Hepatozoon ixoxo* and *H. theileri* form a less well-supported (0.80/75) monophyletic group. The BI statistical information for the bipartitions of this group showed that apart from the 80% probability support, only 13% included *H. thori* n. sp. as part of this clade and 9% showed *H. theileri* formed a clade with *H. involucrum* n. sp. and *H. tenuis* n. sp., thus explaining the low support of this group. Furthermore, *H. ixoxo* and *H. theileri* differ considerably in morphological structure (see Conradie et al. 2017), and if compared with the phylogenetic and morphological...

relationship of *H. involucrum* n. sp. and *H. tenuis* n. sp. (as mentioned above), the former two species are not expected to be sister species. This underlines the importance of increased taxon sampling for these parasites, as the addition of more species to this dataset could result in better-supported clades and the polotomy of the African clade could be resolved. Additionally, faster-evolving markers (e.g. mtDNA) may further explain the biogeography and evolutionary history of these species globally. However, to date, only one haemogregarine, *H. catesbeiana* isolated from the frog *Rana catesbeiana* has mtDNA sequence data available (see Leveille et al. 2014). Although these markers (mtDNA) may be complementary in providing an evolutionary perspective among these parasite groups, a lot more data are required if we want to use similar sized datasets such as those available for 18S rDNA sequences for haemogregarines, especially in terms of vertebrate host diversity (amphibians, reptiles, fishes, birds and mammals) and geographical distribution.

This study highlights the importance of screening anurans from different families and genera in an effort to increase the known biodiversity of these parasites and types of hosts they infect. This study also shows the significance of providing detailed descriptions or reports of species, localities and host records, as we were able to link a species reported by Ball (1967) with *H. thori* n. sp. in the current study based on the morphological details he provided. However, although morphological details are important, the use of them in combination with molecular tools provides a richer dataset with which to work, allowing us to infer historical relationships. Furthermore, if molecular data were available for all the currently recognized species of *Hepatozoon*, those with close morphological characteristics could be correctly distinguished. This stresses the importance of using both of these techniques in combination when describing species, and where possible to provide molecular data for already described species. Future research should, when possible, include faster-evolving genes, identification of possible definitive hosts or vectors and life cycle studies.
