Late-life depression is a common psychiatric disorder in old age. It often has a poor long-term prognosis, more frequently showing a chronic course and a higher relapse rate compared with depression at younger ages. In addition, late-life depression is linked to more medical comorbidity (e.g. cognitive impairment and cardiovascular diseases) and a high risk of mortality. A different phenomenology has been suggested for late-life depression compared with early-life depression. Possible reasons for a different presentation of late-life depression are the overlap of somatic symptoms of depression and physical disease in old age, and sociocultural factors such as the minimal expression of sadness in the current cohort of old people not used to complaining about depressed mood. Also, age-related biological and psychological factors may underlie a different phenomenology of late-life and early-life depression. In three narrative reviews insufficient evidence was found to support a different presentation of late-life depression. In part from that of early-life depression. Major depression in older people may have a more somatic presentation, whereas feelings of guilt and loss of sexual function may be more prevalent in younger people.

Method
A systematic search was conducted in PubMed, Embase and PsycINFO for all studies examining the relation between age and phenomenology of major depression according to RDC, DSM and ICD criteria. Studies were included only if the age groups were compared at the single-item level using the 17-, 21- or 24-item versions of the Hamilton Rating Scale for Depression; a meta-analysis was done for each item of the 17-item scale.

Results
Eleven papers met the inclusion criteria. Older depressed adults, compared with younger depressed adults, demonstrated more agitation, hypochondriasis and general as well as gastrointestinal somatic symptoms, but less guilt and loss of sexual interest.

Conclusions
The phenomenology of late-life depression differs only in part from that of early-life depression. Major depression in older people may have a more somatic presentation, whereas feelings of guilt and loss of sexual function may be more prevalent in younger people.

Declaration of interest
None.
presence at all was extracted. Correlations were extracted when articles provided only correlations between age and single-item scores. When only subsets of the 17 HAM-D items were presented, the authors of more recent studies (published after 1995) were contacted and requested to provide missing data. Where mean scores or correlations were presented separately for men and women or for early-onset and late-onset late-life depression, these were transformed into one weighted combined mean score (s.d.) or correlation coefficients using appropriate formulae.

### Quality assessment

Quality assessment of observational studies in meta-analyses is not usual and there is no consensus regarding the method used. In our study the quality of the included studies was assessed by two authors (J.H., E.G.) using a checklist with the following five criteria:

- (a) both age groups were selected from the same source population;
- (b) population characteristics and inclusion and exclusion criteria were described;
- (c) (semi)structured diagnostic instruments were used;
- (d) difference in overall disease severity between younger and older patients controlled for, or no statistically significant difference in depression severity reported;
- (e) a complete set of 17 HAM-D items was usable or transformable for meta-analysis.

For two criteria weighting was applied, resulting in quality criteria (a) through (c) being coded as 0 or 1 and criteria (d) and (e) as 0, 1 or 2 points, and these criteria were summed to yield a score ranging from 0 to 8 points. If no information was provided as to whether a specific quality criterion was met, it was coded as 0. The cut-off for high or low quality was defined at a score of 5 or more, based on the 60% cut-off point commonly used in quality assessments. Discrepancies between the reviewers were resolved through discussion (J.H., E.G.).

### Statistical analysis

Data management, calculation of effect sizes and quantitative data synthesis were performed using the Comprehensive Meta-Analysis software version 2.0.021 for Windows (www.meta-analysis.com). Odds ratios were calculated for each HAM-D-17 item separately and then used for all mean comparisons. A higher odds ratio means that the particular HAM-D item showed higher prevalence rates and/or greater severity in older v. younger patients. Because considerable heterogeneity was expected, all analyses were performed with the random-effects model that reduces the risk of a type 1 error (as fixed models typically result in narrower confidence intervals). To assess heterogeneity between the studies we calculated the I², which is an indicator of heterogeneity in percentages, and used a value of 50% or over to indicate meaningful heterogeneity. In addition, Q statistics were calculated. A statistically significant Q rejects the null hypothesis of homogeneity and indicates a heterogeneous distribution of effect sizes between studies, meaning that systematic differences, possibly influencing the results, are present. For each HAM-D-17 item two summary estimates were calculated: an estimate based on all studies with usable data (see Fig. 2); and an estimate based on the studies with a quality score of ≥5 points, to estimate the effect of bias and potential confounding. A P-value below 0.01 was considered statistically significant, because of multiple testing for every HAM-D item.

### Results

The search yielded 3037 articles, including 2200 in PubMed, 773 in Embase, 53 in PsycINFO and 11 hand-searched articles. Exclusion of duplicates and irrelevant references after a first screening of the titles and abstracts left 129 potentially relevant articles for further evaluation (Fig. 1). Most articles were excluded because they did not report the outcome of interest (65 studies), most comparing the phenomenology of early-onset v. late-onset late-life depression (20 studies) or examining neurocognitive function rather than depressive symptoms in relation to age (14 studies). Of the 23 excluded articles not concerning a diagnosis of major depression, 21 reported on depressive symptoms, one reported on minor depression and one on dysthymic disorder. Finally, 11 articles were included in this meta-analysis comparing early and late-life major depression. Because some articles did not present all individual items of the HAM-D, three sets of authors were contacted. In one case we received data on the unreported HAM-D items. In the second case the authors were also asked whether two different articles presented data on the same study population. Although our question was not answered we extracted the data, choosing the article with the largest study population. As the HAM-D items ‘weight loss’ and ‘anxiety’ were not presented in this larger study, we extracted these data from the article with the smaller sample size. Data from a third article by this group were also included in this meta-analysis because the study population was without doubt a different group. In the third case, the author was unobtainable for further information concerning not reported or not transformable HAM-D scores and methodological issues. For this latter article, Z scores and P-value statistics were used for the reported HAM-D items.

### Late-life v. early-life depression

The characteristics of the included studies are shown in online Table DS1 and summarised in Table 1; the total number of
Late-life v. early-life depression

participants was 2011. On average, older patients had significantly more severe depression (seven studies with standardised difference in means 0.33, 95% CI 0.13–0.52; $P=0.001$). However, four studies did not report the overall HAM-D severity scores for older and younger patients. In fact, depression severity was particularly greater in older patients in the three studies by Brodaty et al. Apart from this, another study included a population with psychotic depression only, in which both age groups were severely affected. Small et al. reported only on guilt.

With regard to quality assessment we rated nine articles as being of high quality, and two articles as being of lower quality.

EL, early-life depression; HAM-D, Hamilton Rating Scale for Depression; LL, late-life depression; NR, not reported.

a. Quality assessment score.
b. Participants were aged $<40$ or $>70$ years.

Figure 2 presents the pooled odds ratios for the relation between age and symptoms of depression according to the HAM-D-17. Random effect modelling, with a 95% confidence interval and $P<0.01$, showed that older people with major depression, compared with younger people, demonstrated more agitation (OR = 1.84, 95% CI 1.39–4.45, $P<0.001$), general somatic symptoms (OR = 2.01, 95% CI 1.38–2.92, $P<0.001$), gastrointestinal somatic symptoms (OR = 1.58, 95% CI 1.27–1.97, $P<0.001$) and hypochondriasis (OR = 3.13, 95% CI 2.24–4.38, $P<0.001$), but less guilt (OR = 0.52, 95% CI 0.42–0.65, $P<0.001$) and less loss of sexual interest (OR = 0.51, 95% CI 0.37–0.70, $P<0.001$) (Fig. 3). A sensitivity analysis of the nine articles of high quality confirmed these findings.
Fig. 3  Forest plot for the six statistically significant items of the 17-item Hamilton Rating Scale for Depression (HAM-D-17) for the comparison between early-life and late-life depression (P < 0.01).
quality revealed that the significant differences persisted for all six HAM-D-17 items. Another sensitivity analysis excluding studies with more severe depression in older people younger people revealed similar results. Again, removing the study with patients with psychotic depression only did not notably affect the sizes of the odds ratios. Although these were no longer significant for loss of sexual interest and general and gastrointestinal somatic symptoms.

Heterogeneity between studies was not significant for the items agitation ($Q = 6.44$, $P = 0.26$), gastrointestinal somatic symptoms ($Q = 5.17$, $P = 0.52$), guilt ($Q = 8.10$, $P = 0.43$) and loss of sexual interest ($Q = 10.12$, $P = 0.12$), suggesting a homogeneous distribution of effect sizes between the studies. However, for the items hypochondriasis ($Q = 17.90$, $P = 0.02$) and general somatic symptoms ($Q = 13.17$, $P = 0.04$) the I² value was just above 50%, which has a minor effect as we used random-effect models. No study was identified as a consistent outlier for most of the 17 HAM-D items.

### Discussion

The results of this meta-analysis show a partly different phenomenology of late-life depression compared with early-life depression. Older people with major depression demonstrated more agitation, general and gastrointestinal somatic symptoms and hypochondriasis, but less guilt and less loss of sexual interest, compared with younger people with major depression. The difference between the two groups did not reach statistical significance for late insomnia, somatic anxiety and suicidality, which might be due to the small numbers of participants (type 2 error). In general, these results indicate that major depression in older people may have a more somatic presentation, whereas feelings of guilt and loss of sexual function may be symptoms that are more specific for depression at a younger age.

Our results are largely consistent with some earlier studies examining this subject in a different way from comparison at the HAM-D single-item level. For example, older people with major depression were found to be more likely to have somatic symptoms and less likely to have guilt, suicidal and cognitive symptoms. Another study found that older people were more likely to have agitation and late insomnia, whereas younger people were more likely to have increased appetite, weight gain and decreased libido. Similarly, in a study examining exclusively psychotic depression, an increase of agitation and a decrease of suicidality and guilt was found in old age compared with younger age. Husain et al used the 30-item Inventory of Depressive Symptomatology – Clinician Rated and found clinically meaningful differences. In their study older people with non-psychotic major depression had more gastrointestinal symptoms and middle and late insomnia, less irritability and hypersomnia, and were less likely to hold negative cognitions of the self or the future. Others, however, found no difference in the phenomenology of late-life and early-life depression. For instance, no difference in symptoms of major depression was found in an in-patient psychiatric population using the Duke Depression Evaluation Schedule for the Elderly. In addition, Corruble et al using the Montgomery–Åsberg Depression Rating Scale, found similar results in a comparison of the phenomenology of major depression at age $\geq 60$ years vs. $< 60$ years. In a sensitivity analysis we added the seven items that roughly corresponded to the HAM-D items, which did not lead to different conclusions (data not shown). In three reviews without quantitative data analysis it was argued that no clinically relevant difference was found. However, although the studies in these earlier narrative reviews almost overlapped with our studies, some recent articles were not included. Also, these differences in interpretation may relate to the advantages of a meta-analysis over a narrative review that is more prone to subjectivity and bias. Remarkably, in contrast to earlier studies, we did not find differences between older and younger age groups in the HAM-D items loss of insight, work and activity, and psychomotor retardation, which are closely related to the concept of apathy. Also, in spite of what has been suggested by others, no difference was found in depressed mood.

The question arises whether age-related factors modify the presentation of depression or just lead to overlap of somatic symptoms of depression and medical illness, both complicating the diagnosis of late-life depression. For example, not only decrease of sexual desire and sexual function with ageing, but also the lack of a living partner, might explain our finding that older patients had less sexual dysfunction caused by depression compared with younger patients. The expression of more somatic symptoms and less guilt in older patients might be explained by the tendency of the current cohort of older people to express somatic instead of psychological complaints. Alternatively, it might be that the phenomenology of late-life depression is related to specific risk factors; for instance, in the oldest old people, psychomotor retardation and loss of energy were associated with vascular or neurodegenerative risk factors, whereas symptoms such as thoughts of death, as well as sleep and appetite disturbances, were more strongly related to an inflammatory risk factor. However, another study on this subject reported conflicting results. Besides, it is difficult to distinguish apathy and cognitive impairment as distinct clinical entities from depression at old age because of overlap of symptoms. Again, it follows that depression may have been overestimated in these studies, suggesting a different phenomenology based on wrong assumptions.

Several methods have been proposed to resolve the issue of overlap of somatic symptoms of depression and physical illness, complicating the diagnosis of late-life depression. For example, in an inclusive approach all somatic symptoms are included regardless of being primarily due to a medical illness, whereas in an exclusive approach somatic symptoms of depression are excluded and only psychological symptoms are counted for a diagnosis of depression. Next, in an aetiological approach a somatic symptom is only counted if not caused by a medical illness and in a substitutive approach the somatic symptoms are replaced by non-somatic alternatives. Although the HAM-D-17 has been criticised for use in patients with physical illness on the grounds that it includes too many somatic items, the use of this scale is even justified to diagnose post-stroke depression and depression in Parkinson's disease. Moreover, some somatic symptoms were highly sensitive for post-stroke depression.

### Strengths and limitations

Our study has some limitations. First, older patients had on average a higher level of severity of depression than the younger patients, which may account for the slightly different phenomenology in older patients. Although statistically significant, these differences in depression severity were small and therefore not regarded as clinically relevant. In addition, sensitivity analysis excluding studies with significantly more severe depression in older people revealed similar results, suggesting that our results are unlikely to be explained by differences in depression severity. Alternatively, overlapping somatic symptoms of depression and comorbid age-related...
physical disorders may explain the higher scores on depression severity scales in the older population. Second, we could not adjust for comorbid physical disorders in older vs. younger people. Lack of this information means that we cannot be certain whether our findings are related to somatic comorbidity. In fact, all but one study included in-patients, and perhaps older patients with a more somatic presentation were admitted to hospital more often than younger depressed patients in order to exclude an underlying somatic illness. In previous studies, however, differences in the phenomenology of major depression persisted after adjustment for somatic comorbidity. One of these studies was included in our meta-analysis and used an inclusive approach for rating HAM-D items. Third, as studies mainly reported on in-patients it follows that generalisation of our findings to an out-patient or general population is limited. Fourth, a conceptual limitation is the use of strict RDC, DSM and ICD diagnostic criteria for major depression and the HAM-D. Obviously, if distinctive features of late-life depression indeed exist, they would be missed if not included in the HAM-D. Moreover, if depression in older people presents with many symptoms that differ from the DSM or ICD criteria, then these patients might not be diagnosed as having depression and would not have been included in these studies. Finally, this meta-analysis focused on comparing depression at older and younger age, irrespective of age at first onset. It follows that we did not address the question of whether the age at onset of the first depressive episode is related to a specific symptom profile of early- or late-onset late-life depression. However, the studies of Gournellis et al and Brodaty et al compared both early v. late-life depression and early onset v. late onset in late-life depression. Gournellis et al found differences related to both age at onset and current age in which the group of older patients with early-onset depression had an in-between position concerning the extent of differences in hypochondrial ideation and gastrointestinal symptoms compared with a group of older patients with late-onset depression and a group of younger patients with early-onset depression. In the studies by Brodaty et al differences were found related to current age only, but not for age at onset. Furthermore, as late-life depression probably encompasses patients with recurrent depressive episodes and treatment-refractory depression, it is possible that differences in phenomenology between late-life and early-life depression might be more marked when studies include only patients with first depressive episodes. Ideally, these would be prospective cohort studies because recall bias of age at onset is one of the problems of such studies. However, older patients with recurrent depressive episodes might also have a ‘new onset’ distinctive depressive episode, for example related to (vascular) changes in the ageing brain.

Strengths of this meta-analysis include the thorough search resulting in over 2000 participants from 11 studies, the quality of the review process and the consistent findings across studies with generally low heterogeneity. Moreover, we are not aware of previous meta-analyses examining the relation between age and the phenomenology of major depression.

Clinical implications

In summary, the results of this study suggest only in part a different phenomenology of major depression in older people compared with younger adult patients. These findings are relevant for clinical practice, because we should be aware that major depression in older people may present in a more somatic way. This may help our understanding of the phenomenology of late-life depression related to certain risk factors and age at onset, in order to improve recognition and early detection, and refine prevention and treatment of depression in older people.
