Abstract

Serosurveys have established data about the distribution of immunoglobulin G (IgG)-antibodies to pertussis toxin (PT) in various populations. We tried to detect whether small serosurveys in blood donors could serve as a simple and inexpensive means to collect information about the circulation of Bordetella pertussis. We screened every donation in 307 adult blood donors aged 19–69 years for IgG-anti-PT by standardised enzyme-linked immunosorbent assays (ELISA), and the donors were followed between 2014 and 2016 for a total of 426 person-years. When we used a vertical survey with cut-offs of 100, 62.5 and 40 IU/ml, respectively, as an indicator for recent contacts with B. pertussis, nine (2.9%), 22 (7.2%) and 54 (17.6%) of donors had IgG-anti-PT titres above the respective levels. During the horizontal observation period of 426 person years, six significant increases and two conversions were found, which lead to an estimate of 1878 contacts/100.000 person-years (1.9% per year). Median and mean IgG-anti-PT concentrations remained relatively stable from year to year during the observation period. Our findings show that small serosurveys of blood donors offer a simple and cheap method for the surveillance of B. pertussis.

Introduction

Childhood pertussis vaccination with whole-cell pertussis or acellular pertussis vaccines reduced notified pertussis cases about 90%. The greatest burden of morbidity and mortality is found in lower and middle-income countries [1].

The WHO strongly recommends pertussis surveillance for all countries [2], and possible methods for surveillance have recently been summarised [3]. Serosurveys are one of these methods, which have been used in various countries and their role in surveillance has recently been specifically reviewed [4, 5]. However, serosurveys usually depend on a dedicated and expensive study design for collecting the samples. As pertussis is a cyclical disease, vertical serosurveys also only reflect the circulation of the bacteria in the population at a given time point in a specific region, and the differences between trough years and peak years of a cycle can be relevant.

Preparing the plasma pool for the WHO reference material for pertussis serology [6], we screened about 1000 donors yearly in 2002, 2003 and 2005 for immunoglobulin G (IgG)-anti-pertussis toxin (PT) levels of >100 EU/ml. In 2002 and 2003, only 0.7% and 0.3%, respectively, of donors had high IgG-anti-PT levels, whereas in 2005 we found 3.5%. Notification data at that time were only available from eastern German states, such as Mecklenburg-Pomerania, and they corresponded to our findings with incidences of 6.8/100 000 in 2002, 8.7/100 000 in 2003 and 74.6/100 000 in 2005 [7].

Thus, we decided to test an easily available alternative to conventional seroepidemiological studies, and we followed a cohort of blood donors for 3 years to study whether this selected population could be helpful in performing vertical and/or horizontal serosurveys of pertussis in resource-limited areas.

Materials and methods

Blood samples

We screened a randomly selected cohort of blood donors for IgG-anti-PT during 3 years on every donation. Samples from blood donors were anonymised apart from their age and sex. By giving blood, donors had also consented to the use of their samples, and no samples were specifically taken for this study. All procedures for blood donation, sample processing and sample testing were done according to the legal requirements in Germany, and all samples were also tested for the absence of markers for hepatitis B, hepatitis C and HIV infections.

A total of 307 blood donors were regularly followed between 2014 and 2016 for a total of 426 person-years. Due to their more regular donation habits, 81% (m:250/f:57) of the donors...

The median interval between donations was 128 days and the mean interval 86, with a 95% confidence range between 49 and 404 days.

Table 3 shows the antibody levels during the study years (2014–2016), and both median and mean IgG-anti-PT concentrations remained rather stable throughout the study period ($P > 0.1$). Figure 1 shows boxplots of the IgG-anti-PT levels between 2014 and 2016. Differences in antibody levels were not significant between individual donations; however, in donors with seven ($n = 55$) or eight ($n = 25$) donations, antibody levels between the first donation and the seventh or eighth donation significantly decreased ($P < 0.01$ and $P < 0.05$, respectively).

During the observation period of 426 person-years, we observed six significant increases and two conversions, which resulted in an estimate of 1878 contacts/100,000 person-years (1.9%). One of the conversions ($< 2$ to 28 IU/ml) would not have qualified as a suspected contact when usual cut-offs for single serum serology ($>40$ IU/ml) were applied.

**Discussion**

In contrast to seroepidemiological studies for other infectious diseases, pertussis serosurveys are used as a marker for recent contacts to Bordetella pertussis antigens such as PT in a given population. For estimating those recent contacts by a single sample, cut-offs had to be established. This was achieved by Dutch serosurveys carried out repetitively between the 1990s and 2007 [10–12], by EU-wide studies [13] and by analysing a big US serum collection [14]. From these studies, cut-offs of 100–125 IU/ml IgG-anti-PT were suggested for diagnosing recent contacts, and 62.5 IU/ml for not recent contacts [11, 12], as well as 40 IU/ml as a lower limit for triggering additional tests in clinical diagnostics [15]. These cut-offs have been used with slight variations in many other serosurveys worldwide. Seroepidemiology is estimating the frequency of immune responses as a marker for the circulation of B. pertussis in a population at a given time point and in a certain region. This method does not need symptomatic patients and only requires a standardised laboratory technique, which is commercially available [9]. Consequently, seroepidemiological studies of pertussis have been reported from many places of the world [16, 17].

In the EU, a big seroepidemiology study was performed with samples collected between 1995 and 1998 [13]. From former West Germany, 1369 sera were sampled in 1995 among age groups 20 to $>65$ and 3.4% (47) of these contained IgG-anti-PT $\geq 125$ IU/ml. From former East Germany, only 122 samples were available, and 1.6% contained high IgG-anti-PT. When using the 125 IU/ml cut-off for our sample, 7/307 of donors (2.3%) initially had levels $\geq 125$ IU/ml.

Pertussis was a notifiable disease in former East Germany, and it continued to be notifiable since the reunification of Germany [18]. In 2013, pertussis was made notifiable also for former West German states, and the reported incidence rates per 100,000 of
cases that fulfilled the reference definition in former West Germany were 14 (2014), 10 (2015) and 10 (2016) [19]. These notification data correspond nicely to our findings in the blood donors (Fig. 1), but also to the decrease between 2014 and 2015/2016 in donors with many donations.

However, seroepidemiology for pertussis also has limitations: it is not possible to distinguish between antibodies induced by natural contact or by vaccination, and if adolescent and/or adult vaccination programmes are existing, the interpretation of seroepidemiology should consider the individual vaccination status. Due to our strict anonymisation criteria, we had no information about vaccination history of the donors. Pertussis vaccination among adults during the precedent 10 years was assessed by a survey performed between 2008 and 2011 [20]. Here, 12.5% coverage was found, ranging between 28.4 in the age group 18–29 and 7.5% in the age group 60–69. Adolescent vaccination was recommended in Germany in 2000 for adolescents aged 11–18, and in 2008, it was recommended that all adults receive one dose of Tdap. A more recent study performed in 2012–2013 found that only 7.6% of the overall adult population had had a pertussis vaccination during the last decade [21]. As a consequence, we would assume that our data were not intensively biased by recent Tdap vaccination.

Sampling can introduce another bias in respect to age groups and region [3]. Our sample was restricted to adults in Krefeld, a city in North Rhine-Westphalia on the western border of Germany close to the Netherlands, and so our data reflect the seroepidemiology of pertussis only in this area.

Irrespective of these limitations, serosurveys in blood donors offer a simple method for estimating recent contacts to B. pertussis antigens, and our data show that they are vertically and horizontally applicable. As blood donation services are widespread in almost all countries, this simple method may produce estimates of pertussis circulation in those parts of the world, where data on pertussis circulation and incidence are currently not available.

Financial support. This study was supported by a grant from the ’Robert-Koch-Institut‘ (Federal Institute for infectious and non-infectious diseases) as part of the ’Konsilfahrbar Pertussis‘.

Conflict of interest. None.
