The cardiovascular, metabolic and hormonal changes accompanying acute starvation in men and women

BY J. WEBBER AND I. A. MACDONALD

Department of Physiology and Pharmacology, University of Nottingham Medical School, Clifton Boulevard, Nottingham NG7 2UH

(Received 5 February 1993 – Revised 28 April 1993 – Accepted 10 May 1993)

The effect of fasting for 12, 36 and 72 h was studied in twenty-nine healthy subjects (seventeen women and twelve men). Measurements were made of cardiovascular variables, metabolic rate, respiratory exchange ratio, plasma metabolites, insulin, thyroid hormones and catecholamines. During starvation there were no significant changes in blood pressure, whilst heart rate (beats/min) increased at 36 h and remained elevated after 72 h (12 h 62.5 (SE 1.8), 36 h 68.0 (SE 1.9), 72 h 69.2 (SE 1.8); P < 0.001). Forearm blood flow (FBF) increased progressively from 3.32 (SE 0.20) to 6.21 (SE 0.46) ml/100 ml per min (P < 0.001). Resting metabolic rate (kJ/min) was significantly increased after 36 h of starvation (12 h 4.60 (SE 0.14), 36 h 4.88 (SE 0.13), P < 0.001), but was not significantly different from the 12 h value after 72 h (72 h 4.72 (SE 0.15) P = 0.06). The respiratory exchange ratio fell progressively from 0.80 to 0.76 to 0.72 (P < 0.001). Blood glucose fell, whilst plasma glycerol and β-hydroxybutyrate rose and plasma lactate did not change. Plasma insulin and free triiodothyronine fell during starvation. Plasma adrenaline and noradrenaline were unchanged at 36 h, but were significantly increased after 72 h. Both sexes showed a similar pattern of response to starvation, although absolute values of blood pressure, forearm blood flow, metabolic rate and plasma catecholamines were higher in men than women. Acute starvation produces profound cardiovascular and metabolic changes which are not explained by the accompanying hormonal changes.

Starvation: Metabolic rate: Sex differences: Man

There is increasing evidence that the sympathetic nervous system (SNS) and catecholamines released from the adrenal medulla play a role in the control of energy expenditure in man. This regulatory function may be of major importance in the adaptations which occur during under- and overnutrition. It has long been known that prolonged undernutrition and fasting lead to a reduction in resting metabolic rate (RMR). This is due both to a decrease in body mass and to a fall in the energy expenditure of the remaining body tissue. The mediators of this latter process are uncertain but may include changes in thyroid hormone levels.

Demonstrating the role of the SNS in controlling energy expenditure in the resting state in healthy, normally-nourished individuals has been difficult. Some studies have shown a small reduction in RMR during β-blockade (Welle et al. 1991), whilst others have failed to show such an effect (Vernet et al. 1987). However, a clearer picture emerges when one examines stimulated thermogenesis. The SNS is activated following glucose ingestion (Berne et al. 1989) and β-blockade reduces the increment in metabolic rate seen in this situation (Astrup et al. 1989). Although RMR in the normally-fed state may not be much influenced by sympathoadrenal activity, manipulation of nutritional intake may cause more marked changes. Experimental work in rats has shown that fasting leads to suppression of SNS activity (as assessed by the turnover rate of tritiated noradrenaline in specific tissues; Landsberg & Young, 1985), whilst refeeding reverses these changes. In man
a similar pattern of changes in whole-body plasma noradrenaline turnover has been demonstrated during underfeeding and overfeeding (O'Dea et al. 1982).

The physiological changes accompanying short-term starvation in man have not been well characterized. During early starvation there is a profound natriuresis and only after a period of 3–5 d does Na conservation occur (Boulter et al. 1973). Thus, unless salt supplementation is provided during this time-period, an obligatory diuresis and consequent volume depletion will occur. This will lead to compensatory cardiovascular reflexes and concomitant activation of the SNS, hence confounding any nutritionally-related (starvation) SNS changes. Where Na intake has remained constant, dieting and consequent weight loss in obese patients has been shown to reduce blood pressure as well as indices of SNS activity (Jung et al. 1979; Andersson et al. 1991). In normal-weight subjects the picture is less clear. Recent work has suggested there may be a paradoxical increase in RMR early in starvation (Mansell & Macdonald, 1990) as well as increased limb blood flow. What factors mediate these changes are uncertain and in that study none of the hormonal changes seen could explain the observed alterations. In addition, recent studies have suggested there may be significant gender differences in the responses to metabolic stresses such as fasting (Clore et al. 1989) and hypoglycaemia (Amiel et al. 1993). The present study was designed, therefore, to examine the metabolic and physiological correlates of short periods of starvation in men and women, and to see whether changes in plasma catecholamines or other hormones could provide a satisfactory explanation of them.

**METHODS**

Twenty-nine healthy (twelve men), non-obese subjects (women: mean body mass index (weight/height$^2$) 23.2 (SE 0.6) kg/m$^2$, mean age 21.7 (SE 0.7) years; men: mean body mass index 22.5 (SE 0.7) kg/m$^2$, mean age 25.8 (SE 1.2) were recruited for the study. None was taking any medication other than the oral contraceptive pill. All gave written informed consent to the study which was approved by the University of Nottingham Medical School Ethical Committee.

The subjects were each studied on three occasions, after either a 12, 36, or 72 h fast, the 12 h (overnight) fast being taken as the postabsorptive control period against which the values at 36 and 72 h were compared. The studies were done in random order and there was a gap of at least 7 d normal food intake between each fasting period. All the women were studied during the follicular phase of the menstrual cycle. During the fasting period subjects were allowed water *ad lib.*, proprietary flavoured carbonated drinks (One Cal; RHM Foods, Hartlepool) and black decaffeinated tea and coffee without sugar. Whilst fasting, subjects consumed 80 mmol Na and 50 mmol K daily as slow-release tablets to minimize the potentially confounding effects of fluid deprivation and intravascular volume depletion on SNS activity and cardiovascular reflexes.

Studies took place in a temperature-controlled room (28°) with the subjects wearing a T-shirt and shorts only. On arrival subjects rested supine whilst intravenous cannulas were inserted under local anaesthetic, and the monitoring equipment attached. For blood sampling a cannula was inserted retrogradely into a vein on the dorsum of the hand and kept patent with a slow-running infusion of saline (154 mmol NaCl/l). This hand rested in a warm-air box (55–60°) to obtain ‘arterialized’ venous blood samples (McGuire et al. 1976). Continuous recordings of $O_2$ consumption and $CO_2$ production were made using a ventilated-canopy indirect calorimeter (Fellows & Macdonald, 1985). From the respiratory exchange data, calculations of metabolic rate (Weir, 1949) and respiratory exchange ratio (RER) were made. Heart rate (HR) was recorded from an electrocardiogram, and brachial arterial blood pressure was measured using an automated sphygmomanometer (Accutorr.
ACUTE STARVATION AND METABOLIC CHANGES IN MAN

Right forearm blood flow (FBF) was determined by venous occlusion plethysmography using a mercury-in-rubber strain gauge (Whitney, 1953) with an arterial occlusion cuff at the wrist.

Indirect calorimetry was commenced after the subjects had been supine for at least 30 min and was continued for 1 h. The mean values for the last 30 min were used in the calculation of RMR and RER. During the last 30 min measurements of FBF and blood pressure were taken. At the end of this period two samples of arterialized venous blood were withdrawn 10 min apart. Immediately after each blood sample had been taken arterialized glucose concentrations (YSI 23 AM; Yellow Springs Industries, Ohio 45387, USA) were measured. A portion of each arterialized blood sample was deproteinized in 0-1 m-HClO₄, the supernatant fraction being stored at −20° for later analysis of lactate (coefficient of variation (CV) 7-2%), β-hydroxybutyrate (CV 5-6%) and glycerol (CV 7-0%) levels (Lloyd et al. 1978). The remainder of the arterialized blood sample was centrifuged at 4° and the plasma separated. Plasma (2 ml) was mixed with 75 μl EGTA glutathione (antioxidant) and stored at −80° for subsequent determination of adrenaline and noradrenaline concentrations using HPLC with electrochemical detection (Macdonald & Lake, 1985). Intra-assay CV were 6 and 4% for adrenaline and noradrenaline respectively; inter-assay values were 10 and 8% respectively. Plasma was stored at −20° for subsequent determination of free triiodothyronine (FT3; CV 6-0%) and free thyroxine (FT4; CV 3-9%; Amerlex M; Kodak Clinical Diagnostics Limited, Mandeville House, Amersham, Bucks.) and insulin levels (CV 11-7%, mean control 7-1 mU/l; Coat-a-Count; DPL Division, Euro/DPC Limited, Abingdon Business Park, Abingdon, Oxon.).

Statistical analysis of the results was performed by one-way analysis of variance (ANOVA) to look at the changes over time for the group as a whole and for men and women separately, and by multivariate analysis of variance (MANOVA) to compare men and women and their responses. When significant differences were found with ANOVA paired t tests were used to compare individual time points. The package Minitab (Minitab Inc., State College, PA, USA) was used for all statistical calculations.

RESULTS

There was a gap of at least 1 week of normal dietary intake between each period of starvation and in no subject were all three studies completed in a period less than 5 weeks. The studies were carried out using a randomized, balanced design, with no discernible order effect.

Cardiovascular changes

There was no significant change in systolic blood pressure (SBP) during the 72 h of starvation (Fig. 1). SBP was higher in men than women both basally (111-8 v. 103-4 mm Hg, P < 0.001) and at 36 and 72 h of starvation (sex effect P < 0.001, MANOVA). There was no sex difference in the SBP response to starvation. Diastolic blood pressure (DBP) tended to fall progressively over this time-period (from 54-3 to 52-9 to 52-3 mm Hg) but this did not reach significance (time effect P = 0.14, ANOVA). DBP was higher in men than women (sex effect P = 0.002, MANOVA), but the response to starvation was the same in both sexes.

HR increased during starvation from 62-5 to 68-0 to 69-2 beats/min (time effect P < 0.001, ANOVA). The HR at 36 h was significantly greater than that at 12 h (P = 0.001), but there was no further significant increase at 72 h (P = 0.35). There was no sex difference in HR, nor in the HR response to starvation.

FBF rose progressively from 3-32 to 4-87 to 6-21 ml/100 ml per min (time effect P < 0.001, ANOVA). FBF at 36 h was greater than at 12 h (P < 0.001) and that at 72 h was
Fig. 1. Mean heart rate, forearm blood flow, systolic blood pressure and diastolic blood pressure for the group as a whole (□), and for men (□) and women (▪) separately, after 12, 36 and 72 h of starvation. Values are means with their standard errors represented by vertical bars. Mean values for the 36 and 72 h periods were significantly different from that at 12 h, for the group as a whole, and for men and women separately: * P < 0.05, ** P < 0.01, *** P < 0.001. greater than the 36 h value (P = 0.003). FBF was higher in men than women (sex effect P < 0.001, MANOVA) and there was a greater increase in response to starvation in men (sex × time effect P = 0.03, MANOVA).

Metabolic changes
For the group as a whole RMR rose from 4.60 kJ/min at 12 h to 4.88 kJ/min at 36 h and then fell again to a value of 4.72 kJ/min at 72 h (Fig. 2; time effect P < 0.001, ANOVA). The 36 h value was significantly greater than that at 12 h (P < 0.001), but the 72 h value was not significantly different from the 12 h value (P = 0.06). At 72 h the RMR was less than that at 36 h (P = 0.025). Absolute RMR (kJ/min) was greater in men than women (sex effect P < 0.001, MANOVA), but there was no sex difference in the fasting response. When men and women were analysed separately RMR did not change significantly in men over the 72 h period (time effect P = 0.204, ANOVA), but in women there was a significant

Duration of starvation (h)

Resting metabolic rate (kJ/m²)

Fig. 2. Mean resting metabolic rate and respiratory exchange ratio for the group as a whole (□), and for men (□) and women (■) separately, after 12, 36 and 72 h of starvation. Values are means with their standard errors represented by vertical bars. Mean values for the 36 and 72 h periods were significantly different from that at 12 h, for the group as a whole, and for men and women separately: * P < 0.05, *** P < 0.001. For details of subjects and procedures, see pp. 438–439.

change (time effect P < 0.001, ANOVA). RER fell progressively (Fig. 2; time effect P < 0.001, ANOVA). There were no sex differences in RER, or its pattern of change during fasting.

Blood glucose fell from 4.48 to 3.81 to 3.10 mmol/l (Fig. 3; time effect P < 0.001, ANOVA). There were no sex differences in blood glucose, or its pattern of change during starvation.

Blood glycerol rose during starvation (Fig. 3; time effect P < 0.001, ANOVA). There was a significant difference between the 12 and 36 h values (P = 0.001), but not between the 36 and 72 h values (P = 0.72). Both sexes had similar values of glycerol at all time-points.

Blood lactate did not vary during starvation (Fig. 3). There were no sex differences in absolute values, or in response to starvation.

There was a progressive rise in β-hydroxybutyrate levels during starvation (Fig. 3; time effect P < 0.001, ANOVA). No sex differences were demonstrated for β-hydroxybutyrate.

Hormonal changes

Plasma adrenaline levels increased during starvation (Fig. 4; time effect P = 0.015, ANOVA). There was no significant difference between the 12 h and 36 h values (P = 0.068), but the 72 h value was greater than that at 12 h (P = 0.006). Adrenaline was higher in men than in women (sex effect P = 0.017, MANOVA). The change in adrenaline over starvation was not different in the two sexes.
Fig. 3. Mean blood glucose, lactate, β-hydroxybutyrate and glycerol for the group as a whole (□), and for men (■) and women (○) separately, after 12, 36 and 72 h of starvation. Values are means with their standard errors represented by vertical bars. Mean values for the 36 and 72 h periods were significantly different from that at 12 h, for the group as a whole, and for men and women separately: ** P < 0.01, *** P < 0.001. For details of subjects and procedures, see pp. 438–439.

Plasma noradrenaline levels changed with starvation (Fig. 4; time effect P < 0.001, ANOVA). There was no change in levels at 36 h compared with those at 12 h (P = 0.89), but the levels at 72 h were significantly greater than those at both 12 and 36 h (P = 0.002 and P < 0.001 respectively). Noradrenaline levels were higher in men than women (sex effect P = 0.001, MANOVA). The response to starvation was the same in men and women.

Plasma insulin fell progressively during starvation (Fig. 5; time effect P < 0.001, ANOVA). There were no sex differences in absolute values or the response to starvation. FT3 levels gradually fell (Fig. 5; time effect P < 0.001, ANOVA). FT3 levels were significantly higher in men compared with women (sex effect P < 0.001, MANOVA). There was no sex difference in the response to starvation. FT4 levels did not change during starvation (Fig. 5). FT4 was higher in men than women (sex effect P < 0.001, MANOVA). There was no sex difference over time.

FT3: FT4 fell with starvation from 0.40 to 0.35 to 0.27 at 12, 36 and 72 h respectively (time effect P < 0.001, ANOVA).

DISCUSSION

The present study confirms previous work concerning the cardiovascular, metabolic and hormonal changes accompanying acute starvation. In providing data on all these variables it also allows inferences to be made concerning the relationships between them. There was no significant change in SBP over the 72 h fast, but there was a tendency for DBP to fall. This dissociation between the effects of acute starvation on SBP and DBP has been noted previously in studies on healthy men (Bennett et al. 1984). The explanation is probably the marked limb vasodilatation that is seen in starvation rather than any effect due to volume depletion, this being prevented by concomitant salt supplementation. In the current study FBF rose progressively, almost doubling by 72 h. Heart rate also increased significantly by 36 h, but there was no further change by 72 h.

An increasing number of studies have demonstrated the increase in RMR seen after 36–48 h of starvation (Mansell & Macdonald, 1990; Mansell et al. 1990), in contrast to the decrease found after more prolonged starvation and undernutrition (Benedict, 1915). Our study confirms this observation and shows that the effect is a transient one which is mostly reversed by 72 h. The likely cause of this elevation in RMR is the energy requirements of gluconeogenesis and ketogenesis, both of which are metabolically relatively expensive.
processes. That our subjects were truly fasting is shown by the progressive fall in RER and in blood glucose, whilst β-hydroxybutyrate rose progressively. Blood glycerol rose reflecting increasing lipolysis at 36 h but there was no further change at 72 h, perhaps because of the increasing utilization of glycerol as a gluconeogenic substrate and also due to feedback inhibition of lipolysis by the high blood ketone levels (Moller et al. 1990).

The continued fall in plasma insulin and FT3 levels whilst FT4 remained unchanged corroborates the findings of other workers (Palmblad et al. 1977; Beer et al. 1989). Although thyroid hormones are likely to have a role in the reduced metabolic rate of prolonged starvation, changes in their plasma levels cannot explain the elevated RMR of early starvation, nor the increase in resting HR seen in the present study.

Plasma adrenaline and noradrenaline were both significantly elevated after the 72 h fast relative to the overnight fasted levels. However, whereas adrenaline levels tended to rise
progressively from 12 to 36 to 72 h, plasma noradrenaline was unchanged at 36 h. Thus, whereas RMR is most elevated after 36 h, plasma noradrenaline, an indirect marker of SNS activity, is unchanged at this time. It would seem unlikely, therefore, that activation of the SNS is responsible for this rise in RMR. However, plasma catecholamine levels may not accurately represent sympathoadrenal activity. Plasma noradrenaline represents the spillover of the neurotransmitter from sympathetic post-ganglionic neurones, with the majority of noradrenaline being cleared by presynaptic re-uptake or by local metabolism (Esler et al. 1990). Thus, an increase in plasma levels may be due to increased production (enhanced SNS activity/increased rate of spillover) or decreased clearance. Other workers have assessed SNS activity by means of measuring muscle efferent sympathetic activity (MSA). Using this technique Andresson et al. (1988) showed that a 48 h fast in obese subjects caused an increase in both plasma noradrenaline (venous) and in MSA, although despite this apparent enhancement of SNS activity SBP and DBP fell dramatically. It should be noted here that the response of obese subjects to fasting may be quite different to normal-weight volunteers. In addition there may be changes in adrenergic sensitivity during starvation which may counteract or enhance any changes in SNS activity. Mansell et al. (1990) showed that the thermogenic and lipolytic responses to an adrenaline infusion were enhanced after a 48 h fast. However, there were no changes in the cardiovascular responses to adrenaline after the fast. Thus, there may be discrete activation of the SNS to different tissues such that there is not an all-or-nothing whole-body response.

The main sex differences noted in the present study were the elevated plasma levels of adrenaline, noradrenaline, FT3 and FT4 in men compared with women. That RMR was higher in men mainly reflects their larger size and greater fat-free mass. Although when analysed by MANOVA there was no sex difference in the changes in RMR during starvation, when the two groups were analysed separately there was no change in RMR in men after 36 and 72 h, but in women RMR was increased at 36 h and then decreased after 72 h to a value not significantly different from that at 12 h. No differences in the hormonal responses to starvation in the present study account for this disparity, but previous work has noted higher levels of glucagon in women than men (Merimee & Fineberg, 1973), which may perhaps enhance rates of gluconeogenesis in women compared with men. However, in that study plasma glucose fell to lower values in women than in men after 36 and 72 h of
fasting (so accounting for the greater rise in glucagon), whereas the present study did not show any difference in the pattern of fall of blood glucose. The explanation for this disparity is not clear, but may include different ages of the experimental subjects and differing degrees of physical fitness and activity during the study. The current study used arterialized venous blood, whilst Merimee & Fineberg used venous plasma samples. In well-insulinized subjects venous blood values may be lower than arterialized values, but in fasting subjects there is unlikely to be any significant difference between the two sampling sites. Moreover, values for whole-blood glucose are normally 10% lower than those for plasma glucose and, thus, lower values would be expected in the present study.

The only significant sex difference in the response to starvation was the greater FBF increment in men which may reflect a greater proportion of muscle compared with adipose tissue in the forearm of men. This argument implies that muscle blood flow increases more than that of adipose tissue during starvation, but data to confirm this are lacking. Only one study has examined adipose tissue blood flow in humans (four obese women) during acute starvation and there was a doubling of flow after a 4 d fast from 1·3 to 2·4 ml/100 ml per min (Nielson et al. 1968). Basal blood flow, therefore, may be lower in subcutaneous adipose tissue than in skeletal muscle and, hence, any increase in blood flow to this tissue will have less overall effect on total limb blood flow than similar changes in the muscle component. In the current study total FBF doubled after a 72 h fast (3·32–6·21 ml/100 ml per min), but the separate contributions of muscle and adipose tissue were not assessed.

The overall pattern of changes is summarized in Table 1. This shows that whilst RMR is elevated at 36 h, there is no change in catecholamines at this time-point and FT3 is actually reduced in comparison with 12 h. Then, after 72 h of fasting RMR is not significantly different to the 12 h level, but noradrenaline (a marker of SNS activity) is increased. Likewise, the elevation in HR is mostly complete at 36 h and does not seem to be directly related to any of the hormonal changes observed. It is of note that the two variables which continued to rise progressively throughout the period of starvation were FBF and blood β-hydroxybutyrate levels. We have some data that infusion of β-hydroxybutyrate can raise FBF (J. Webber and I. A. Macdonald, unpublished results), although the mechanisms behind this are unclear. The transient elevation in RMR is probably mediated by enhanced rates of gluconeogenesis and ketogenesis, before the effect of these processes is overwhelmed by the profound changes in thyroid status which contribute to the slowing of cellular metabolism that predominates in more prolonged starvation.

In conclusion, the present study has shown that a 72 h fast in normal-weight subjects causes marked cardiovascular, metabolic and hormonal changes. However, the pattern of changes observed does not readily allow a hormonal explanation of the phenomena. In particular, sympathetic activity (as assessed by plasma catecholamine levels) does not correlate with elevations in RMR, HR or FBF. These data point to the need to measure other indices of sympathetic activity both of the whole body and of individual organs, as well as to look for other mediators of the adaptations which occur during starvation.

The authors are grateful to Mr S. Brown for measuring insulin, FT3 and FT4 concentrations, to Linda Ashworth for measuring intermediary metabolites, and to Ms J. Taylor and Mr D. Forster for catecholamine analyses. They are also grateful to all their subjects for giving of their time and giving up their food. The study was supported by a project grant from the Wellcome Trust.
