Optimum nutrition: thiamin, biotin and pantothenate

David A. Bender
Department of Biochemistry and Molecular Biology, University College London, Gower Street, London WC1E 6BT, UK

The metabolism of glucose is deranged in thiamin deficiency, but once any deficiency has been corrected there is no further effect of increased thiamin intake on the ability to metabolise glucose through either pyruvate dehydrogenase (EC 1.2.4.1) and the citric acid cycle, or the pentose phosphate pathway, in which transketolase (EC 2.2.1.1) is the thiamin-dependent step. It has been suggested that the Wernicke-Korsakoff syndrome is associated with a genetic variant of transketolase which requires a higher than normal concentration of thiamin diphosphate for activity. This finding would suggest that there may be a group of the population who have a higher than average requirement for thiamin, but the evidence is not convincing. There are no estimates of biotin requirements, but either coenzyme saturation of erythrocyte pyruvate carboxylase, or the excretion of 3-hydroxy-isovalerate (perhaps after a test dose of leucine) could be used to assess requirements in depletion–repletion studies. Biotin deficiency leads to impaired glucose tolerance, but it is unlikely that glucose tolerance could be used to assess optimum biotin status, since other more common factors affect glucose tolerance to a greater extent. Plasma triacylglycerol and non-esterified fatty acids are moderately elevated in pantothenic acid deficiency. However, this is unlikely to be useful in assessing pantothenate status, since again, other more common factors affect plasma lipids. To date there are no biochemical indices of adequate pantothenate nutrition, and no estimates of requirements.

In the absence of any clear definition of optimum nutrition, and given the impracticability of performing whole-life studies, we have to investigate the metabolic functions of the nutrients in order to determine which, if any, may provide markers of a level of intake that could be considered to be desirable or optimum, rather than being simply adequate to prevent deficiency. It is also relevant to consider whether inadequate intake of the nutrient in question may be sufficiently important to warrant investigation, or whether average intakes are so obviously greater than optimum levels of intake that further investigation is probably irrelevant.

Thiamin

Thiamin has two distinct functions. Thiamin diphosphate (TDP) is the coenzyme for pyruvate dehydrogenase (EC 1.2.4.1) and transketolase (EC 2.2.1.1) in carbohydrate metabolism, or-ketoglutarate dehydrogenase (EC 1.2.4.2) in the citric acid cycle, and branched-chain keto-acid dehydrogenase (EC 1.2.4.4) in the metabolism of the branched-chain amino acids. Thiamin triphosphate (TTP) acts in nerves (and possibly also muscle) to activate a chloride ion channel. Bettendorf et al. (1993b, 1994) showed that the formation of TTP in brain-membrane-vesicle preparations was correlated with chloride uptake. In neuroblastoma cells in culture the addition of TTP results in activation of the chloride ion channel, which is not reversed by washing out, suggesting that it acts by phosphorylation of the chloride-channel protein (Bettendorf et al. 1993a). Impaired formation of TTP may be a factor in the neurological signs of both beriberi and Wernicke-Korsakoff syndrome, although Thornber et al. (1980) reported that TTP was preserved in the brains of thiamin-deficient lambs, at the expense of TDP and free thiamin. There are no reports of TTP concentration in analyses of brains of patients with Wernicke-Korsakoff syndrome, presumably because of its instability post mortem, and at present there is no way of using TTP or membrane chloride permeability to assess thiamin nutritional status.

The role of TDP in pyruvate dehydrogenase was elucidated in the 1930s. Thiamin deficiency results in
Impaired activity of transketolase has been implicated as a factor in the central nervous system lesions of Wernicke’s encephalopathy, a condition that may be considerably more prevalent than has been believed. Harper (1979) reported that Wernicke’s encephalopathy had only been diagnosed in 13 % of a series of patients in whom brain lesions were detected post mortem. There is considerable international variation in the prevalence of the Wernicke-Korsakoff syndrome, which is not accounted for by variations in alcohol consumption, and a body of evidence to suggest genetic susceptibility (Zubaran et al. 1997). There are two genes for transketolase: the most investigated is on chromosome 3, but Cay et al. (1996) reported a second transketolase gene on the X chromosome. If this X-linked gene were associated with susceptibility to the Wernicke-Korsakoff syndrome, there would be a sex-linked (maternal) pattern of inheritance. However, most of the evidence suggests autosomal inheritance (Mukherjee et al. 1987), so it is likely that it is the gene on chromosome 3 that is important.

Blass & Gibson (1977) reported that the affinity of transketolase for TDP was approximately 10-fold lower in cultured fibroblasts from patients with Wernicke-Korsakoff syndrome than in those from control subjects, suggesting that there may be a genetic polymorphism in transketolase that would result in a subgroup of the population having higher than average thiamin requirements. This finding is akin to the thiamin-responsive variant of maple-syrup-urine disease, where the affinity of branched-chain keto-acid dehydrogenase is considerably lower than normal; in this case thiamin supplements of approximately 100 mg/d are required (Scrivet et al. 1971).

In support of the suggestion of a variant transketolase associated with the Wernicke-Korsakoff syndrome, Jayasimhan et al. (1987) reported that a significant number of elderly patients with acute dementia, as well as chronic alcoholics, showed not only a higher than normal transketolase activation coefficient (indicative of thiamin deficiency), but also showed a further increase in enzyme activity when erythrocyte lysates were incubated with 3 mmol thiamin, compared with the usual 0.3 mmol/l used for the transketolase activation test.

By contrast, Nixon et al. (1984) reported no difference in the affinity of transketolase for TDP between patients with Wernicke-Korsakoff syndrome and controls. They demonstrated a variety of different patterns of electrophoretically-separable forms of transketolase in normal subjects; one pattern was found in thirty-nine of forty-two patients with the Wernicke-Korsakoff syndrome, but only eight of thirty-six control subjects. However, Blansjaar et al. (1991) reviewed a series of investigations and concluded that there was little evidence to support a genetic abnormality of transketolase associated with Wernicke-Korsakoff syndrome.

McCool et al. (1993) and Martin et al. (1995) demonstrated that multiple electrophoretically-separable forms of transketolase were not the result of variant alleles, tissue-specific isoenzymes or differential splicing of mRNA, and suggested that there were differences in either the assembly of the functional holoenzyme or post-synthetic modification
of the protein. Support for this suggestion comes from the studies of Wang et al. (1997), who expressed the human transketolase gene in Escherichia coli, and noted that formation of the normal active enzyme required a cytosolic factor derived from human cells, and this factor was absent from, or inactive in, cells from a Wernicke-Korsakoff patient, which showed enhanced sensitivity to thiamin deficiency in culture.

Alzheimer’s disease

Perhaps partly because thiamin is effective in treating the Wernicke-Korsakoff syndrome, it has been used empirically in treatment of Alzheimer’s disease and other dementias. There is some evidence to suggest that thiamin deficiency may be a factor in Alzheimer’s disease.

Mastrogiacoma et al. (1993) reported low activity of α-ketoglutarate dehydrogenase in brains from patients with Alzheimer’s disease, and increased stimulation by TDP added in vitro, suggesting thiamin deficiency. Héroux et al. (1996) reported reduced activity of pyruvate and α-ketoglutarate dehydrogenases and transketolase, as well as thiamin mono- and diphasphates, suggesting an impairment of thiamin metabolism. By contrast, Mastrogiacoma et al. (1996) reported normal activities of thiamin-metabolizing enzymes, and normal concentrations of free thiamin and thiamin monophosphate in all three cortical regions in Alzheimer’s disease. They suggested that the 18–21% reduction in TDP was due to impaired energy-yielding metabolism.

Mastrogiacoma et al. (1993) noted a significant negative correlation between α-ketoglutarate dehydrogenase activity and the number of neurofibrillary tangles in the cortex. Calingasan et al. (1996) reported clusters of amyloid pre-cursor protein and amyloid-precursor-like protein in the brains of thiamin-deficient rats and mice, similar to those seen in the brains of patients with Alzheimer’s disease, but noted that there was no immunochemical or histochemical evidence of amyloid precursor proteins in the brains of patients with Wernicke-Korsakoff syndrome.

There is little evidence that thiamin supplements have any beneficial effect in Alzheimer’s disease; a number of studies were summarized by Blass et al. (1992) who stated that ‘treatment with large doses of thiamin has not been effective in elderly patients with Alzheimer’s disease, and there seems to have been no further report from that there was a mild beneficial effect of 3–8 g thiamin/d, although there is some evidence that inadequate thiamin nutrition may be a factor in sudden infant death. Johnson et al. (1990) reported that the liver biotin content in children who had died from no known cause was approximately 75% that in children who had died from a known cause. The fatty liver and kidney syndrome, which can cause sudden death of flocks of chicks, is associated with biotin deficiency (Bannister, 1976), and biotin deficiency can lead to skin and hoof lesions in pigs.

Biotin functions as the coenzyme for four carboxylases: pyruvate carboxylase (EC 6.4.1.1), acetyl-CoA carboxylase (EC 6.4.1.2), propanoyl-CoA carboxylase (EC 6.4.1.3) and methylcrotonyl-CoA carboxylase (EC 6.4.1.4). Much of our knowledge of the metabolic disturbances that may be associated with biotin deficiency, and which might therefore provide sensitive markers of status, has come from studies of children with multiple carboxylase deficiency as a result of genetic diseases which lead to functional deficiency despite an adequate dietary intake. Holocarboxylase synthetase (EC 6.3.4.10) catalyses the covalent attachment of biotin to a lysyl residue in the carboxylase apo-enzymes; lack of this enzyme results in total absence of all four carboxylases, and is fatal in early life (Nyhan, 1987). When biotin-containing enzymes are catalysed, the biotin is released as biocytin (biotinyl ε-amino-lysine); this is normally hydrolysed by biotinidase (EC 3.5.1.12), and there is considerable conservation of the biotin released in this way. Children who lack biotinidase again suffer from multiple carboxylase deficiency, but can be treated with relatively large supplements of biotin, to replace that lost as biocytin rather than it being salvaged. However, they do suffer some long-term neurological damage (Hymes & Wolf, 1996).

In addition to its coenzyme role, biotin also has effects on gene expression; it reacts with, and binds covalently to, histones. Biotinidase seems to be important here, acting both as an intracellular biotin-binding protein and to catalyse the covalent attachment to histones (Hymes et al. 1995; Hymes & Wolf, 1996). There is some evidence that biotinidase deficiency is strongly teratogenic in experimental animals (Watanabe & Endo, 1984; Watanabe et al. 1995).

Chauhan & Dakshinamurti (1991) have shown that biotin also acts, relatively specifically, to induce the synthesis of glucokinase in fasted rats. Glucokinase (EC 2.7.1.2) is an isoenzyme of hexokinase (EC 2.7.1.1) with a high Michaelis constant (Km) for glucose. In the liver, glucokinase is responsible for the increase in glucose uptake and metabolism; glucokinase deficiency in the fed state; hexokinase has a Km of 0.15 mmol/L, and is therefore saturated with glucose, and acting at a constant rate under all physiological conditions, whereas glucokinase, with a Km of 20 mmol/L, only has significant activity when the concentration of glucose in the portal blood rises after a meal (Stryer, 1995). Apart from the liver, the only other tissue in which glucokinase is known to be expressed is the β-islet cells of the pancreas. Froguel et al.
(1993) studied a series of children with maturity-onset diabetes of the young (an inherited condition). They showed that these children all lacked glucokinase. While their fasting insulin secretion was more or less normal, they were unable to secrete a significantly greater amount of insulin in response to a hyperglycaemic clamp (an infusion of glucose to maintain a plasma concentration of 10 mmol/l). It is likely that glucokinase acts as the initial sensor of increasing glucose concentrations for the stimulation of insulin secretion by the pancreas (Matschinsky et al. 1993). This finding suggests that biotin deficiency may be associated with impaired glucose tolerance (although the impairment of gluconeogenesis as a result of reduced activity of pyruvate carboxylase might lead to fasting hypoglycaemia), and Zhang et al. (1997) have shown that intraperitoneal administration of biotin improves glucose tolerance in rats made diabetic by administration of streptozotocin. Since the β-islet cells are destroyed by streptozotocin, this finding presumably reflects induction of hepatic glucokinase by biotin. It is, however, unlikely that glucose tolerance could be used as an index of optimum biotin status, since the interpretation of results would be confounded by impairment of insulin sensitivity in subjects developing non-insulin-dependent diabetes.

Pyruvate carboxylase is found in erythrocytes, and its activation in vitro by added biotin can be used as an index of status (Bisch et al. 1985). As with other enzyme activation assays, there is normally some apo-enzyme in erythrocytes, so that it might be possible to define the level of intake at which there is 100% saturation of the enzyme, and hence an activation coefficient of 1.0. Pyruvate carboxylase is a key enzyme in gluconeogenesis, as well as being an important anaplerotic reaction for maintenance of an adequate supply of oxaloacetate for citrate cycle activity. Thus, impairment of a result of biotin deficiency might be expected to lead to fasting hypoglycaemia as a result of reduced gluconeogenesis, and ketosis as a result of lack of acetocetate for citrate cycle activity. Fasting hypoglycaemia was proposed as the link between low biotin status and sudden infant death (Johnson et al. 1980), and impaired gluconeogenesis, which is corrected by biotin, is seen in chicks suffering from the fatty liver and kidney syndrome (Bannister, 1976). Impairment of pyruvate carboxylase activity leads to an accumulation of pyruvate, lactate and alanine (Hynes & Wold, 1996); however, this impairment cannot be exploited as a means of assessing optimum biotin status, since the same accumulation of pyruvate metabolites is seen in thiamin deficiency, as a result of impairment of pyruvate dehydrogenase. Furthermore, it is unlikely that intakes of biotin above those needed to prevent deficiency would increase pyruvate carboxylase activity, since the enzyme is strictly regulated by acetyl-CoA, which is an obligatory allosteric activator. It is only active when there is a need for synthesis of oxaloacetate for gluconeogenesis or repletion of the citrate cycle (Stryer, 1995).

Acetyl-CoA carboxylase is an essential enzyme for fatty acid synthesis and elongation, so impairment of its activity would be expected to affect acetyl metabolism. Donaldson (1985) showed that in biotin-deficient chickens there was significantly less incorporation of [14C]acetate into lipids, and a greater proportion of the dose was exhaled as 14CO₂. It is unlikely that this finding could be exploited as a test of optimum biotin nutritional status. Kopinski et al. (1989) showed that the impairment of fatty acid elongation in biotin-deficient pigs with intestinal desaturase activity led to an increase in the monoene: saturated fatty acid value in liver lipids. While there may be similar effects on plasma lipid composition, this ratio is probably too susceptible to the effects of dietary fat intake to provide a useful index of biotin status.

Propionyl-CoA arising from a number of sources, including the metabolism of isoleucine, methionine, the side-chain of cholesterol and (rare) dietary odd-chain fatty acids, is normally carboxylated by propionyl-CoA carboxylase to yield methylmalonyl-CoA, which then undergoes isomerization to succinyl-CoA, a citrate cycle intermediate. Impairment of propionyl-CoA carboxylase leads to urinary excretion of propionate and onward metabolites such as hydroxypropionate, propionyl glycine and methyl citrate. Detection of these acids in urine may therefore provide an index of biotin deficiency; they are not normally detectable. Thus, it is possible that the ability to metabolize a test dose of [13C]propionate may provide a sensitive index of status. Barshop et al. (1991) reported that control subjects exhaled between 46% and 70% of a test dose of [13C]propionate as 13CO₂; however, apart from the endogenous sources of propionate, intestinal bacteria provide a considerable but variable amount, which would lead to unpredictable dilution of the isotope and confound interpretation of the results.

Propionyl-CoA can also compete with acetyl-CoA for incorporation into fatty acids, leading to the formation of odd-chain fatty acids. Mock et al. (1988) reported an increased proportion of 15:0 and 17:0 fatty acids in plasma lipids of patients who were biotin deficient as a result of prolonged total parenteral nutrition, which was normalized by administration of biotin. Proud et al. (1990) showed that the proportion of all odd-chain fatty acids from 15:0 to 25:0 was increased in skin lipids from biotin-deficient rats. This finding suggests that measurement of odd-chain fatty acids in skin or serum lipids might be a useful index of optimum biotin status. However, dietary intake is probably more important than endogenous synthesis of odd-chain fatty acids. Watkins (1988) measured 17:0 levels in liver and heart triacylglycerol from biotin-deficient animals fed on four different sources of fat: maize oil; hydrogenated soya bean oil; a mixture of tristearin, tristearin and tripalmitin; spent restaurant grease. The differences due to dietary fat were considerably greater than those due to biotin deficiency.

Methylcrotonyl-CoA is an intermediate in the metabolism of leucine; it is normally carboxylated, leading eventually to the formation of acetyl-CoA and acetocetate. Impairment of methylcrotonyl-CoA carboxylase activity leads to urinary excretion of methylcrotonate and two outward metabolites, methylcrotonyl glycine and 3-hydroxyisovalerate. The latter acid is an early marker of experimenetal biotin deficiency in rats (Mock & Mock, 1992). 3-Hydroxy-isovalerate is normally excreted in detectable amounts (some 25–42 µmol/24 h). In a human study in which avidin was fed in order to cause biotin depletion, Mock et al. (1997) showed that urinary 3-hydroxy-

Downloaded from https://www.cambridge.org/core. IP address: 54.191.48.80; on 14 Jul 2017 at 12:34:16, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0029665199000567
isovalerate excretion increased 4-fold, while plasma biotin was still (just) within the reference range. Measurement of 3-hydroxy-isovalerate excretion, perhaps combined with a loading dose of its precursor leucine, may provide a sensitive test of optimum biotin nutritional status.

**Pantothenate**

As with biotin, pantothenate deficiency is more or less unknown. The so-called burning foot syndrome (nutritional melagia) in severely-malnourished prisoners of war in the Far East is often assumed to have been due to pantothenate deficiency, but for obvious reasons they were repleted with yeast extract as a source of all B-vitamins rather than being deficient, but for obvious reasons they were repleted with yeast extract as a source of all B-vitamins rather than being used for more precise experimental studies.

Early studies showed that there was loss of fur colour in black and brown rats fed on a pantothenate-deficient diet, and at one time it was known as the anti-grey hair factor. Despite the fact that there is no evidence that loss of hair colour with age in human subjects is related to pantothenate nutrition, it is still added to shampoo. Matsumoto et al. (1991) showed that the administration of pantoyl GABA, homopantothenate or hopanthenate, is used in Japan to enhance cognitive function, especially in Alzheimer’s disease. It acts via GABA receptors to increase acetylcholine release and cholinergic function in the cerebral cortex and hippocampus (Nakahiro et al. 1985). A rare side effect is the development of hepatic encephalopathy (Noda et al. 1991), and the excretion of a variety of dicarboxylates which arise by way of CoA-independent α- and ω-oxidation of fatty acids (Matsumoto et al. 1991). Both the encephalopathy and the dicarboxylic aciduria are reversed by pantothenate, suggesting that homopantothenate may cause pantothenate deficiency. If this suggestion is verified, dicarboxylic aciduria may provide a marker of pantothenate status. However, it is equally possible that the adverse effects are due to a toxic action of homopantothenate which is antagonized by pantothenate.

Pantothenate has two well-defined metabolic roles: in CoA in fatty acid oxidation acetate metabolism, cholesterol and steroid synthesis, and acetylation of drugs; as the prosthetic group of acyl-carrier protein in fatty acid synthesis and efficient conservation of phosphopantetheine arising from catabolism of CoA and acyl carrier protein. Kirschbaum et al. (1990) showed that the increase in liver CoA in fasting in both control and genetically-diabetic mice was due to changes in the activity of pantothenate kinase (EC 2.7.1.13). This enzyme is subject to feedback inhibition by CoA and acyl-CoA, repression by insulin (in the fed state when the need for CoA is lower) and induction by glucagon (in the fasting state when there is a greater requirement for CoA). The availability of pantothenate is unlikely to affect the rate of incorporation into CoA, since there is a Km of the enzyme is 18 μmol/l, and even in severe experimental deficiency most tissues maintain a higher concentration. There is rapid turnover of the prosthetic group of acyl carrier protein (a half-life of the order of 6h) compared with a half-life of apo-acyl carrier protein (6-4d; Volpe & Vagelos, 1973). The phosphopantetheine released from acyl carrier protein is incorporated into CoA, which in turn activates apo-acyl carrier protein as required; presumably the enzymes responsible for this cycling of phosphopantetheine are under hormonal regulation. Wittwer et al. (1990) showed that both plasma triacylglycerol and non-esterified fatty acids are moderately elevated in pantothenate-deficient rats; however, this finding is unlikely to provide the basis for a test of pantothenate status in human subjects.

**Summary**

Especially if there is a genetic polymorphism in transketolase that affects thiamin requirements, there is a need to re-examine current estimates of requirements; probably the only index of status that is available is the transketolase activation assay. While Thurnham (1981) questioned the physiological significance of marginal vitamin deficiency as determined by enzyme activation assays, transketolase activation is at least a marker that can be used to assess saturation of one physiological system. In the case of biotin, it is obviously desirable to have an estimate of requirements or desirable levels of intake; either saturation of erythrocyte pyruvate-CoA carboxylase with its coenzyme or, preferably, 3-hydroxy-isovalerate excretion (perhaps after a test dose of leucine) will provide an index of adequacy. There still seems to be no way of assessing pantothenate status.
