Abstract. We report the results from a systematic search for molecular (OH 119 \(\mu\)m) outflows with Herschel-PACS\textsuperscript{†} in a sample of 43 nearby (\(z < 0.3\)) galaxy mergers, mostly ultraluminous infrared galaxies (ULIRGs) and QSOs. We find that the character of the OH feature (strength of the absorption relative to the emission) correlates with that of the 9.7-\(\mu\)m silicate feature, a measure of obscuration in ULIRGs. Unambiguous evidence for molecular outflows, based on the detection of OH absorption profiles with median velocities more blueshifted than \(-50\) km s\(^{-1}\), is seen in 26 (70\%) of the 37 OH-detected targets, suggesting a wide-angle (\(\sim 145^\circ\)) outflow geometry. Conversely, unambiguous evidence for molecular inflows, based on the detection of OH absorption profiles with median velocities more redshifted than \(+50\) km s\(^{-1}\), is seen in only 4 objects, suggesting a planar or filamentary geometry for the inflowing gas. Terminal outflow velocities of \(~ -1000\) km s\(^{-1}\) are measured in several objects, but median outflow velocities are typically \(~ -200\) km s\(^{-1}\). While the outflow velocities show no statistically significant dependence on the star formation rate, they are distinctly more blueshifted among systems with large AGN fractions and luminosities \([\log (L_{\text{AGN}}/L_{\odot}) \geq 11.8 \pm 0.3]\). The quasars in these systems play a dominant role in driving the molecular outflows. In contrast, the most AGN dominated systems, where OH is seen purely in emission, show relatively modest OH line widths, despite their large AGN luminosities, perhaps indicating that molecular outflows subside once the quasar has cleared a path through the obscuring material.

1. Introduction

Studies conducted in the past three years are shedding new light on the wind phenomenon in the local universe: (1) Early results from our Herschel guaranteed time key program SHINING (PI Sturm) have revealed far-infrared (FIR) OH features with P-Cygni profiles indicative of massive molecular outflows in a number of ULIRGs (Fischer et al. 2010; Sturm et al. 2011, hereafter F10 and S11, respectively; also González-Alfonso et al. 2012; González-Alfonso et al. 2014). In a few of these objects, particularly those with dominant AGN such as Mrk 231, the nearest quasar known, the terminal outflow velocities exceed 1000 km s\(^{-1}\) and the outflow rates (up to \(~1000\) M\(_{\odot}\) yr\(^{-1}\)) are several times larger than the infrared-based SFRs. (2) Independent, spatially resolved CO-emission observations of Mrk 231 with the IRAM/PdB mm-wave interferometer (Feruglio et al. 2010; Cicone et al. 2012; it has also been mapped in HCN, HCO\(^+\), and HNC by Aalto et al. 2012) have confirmed this outflow and deduced mass outflow rates of \(~700\) M\(_{\odot}\) yr\(^{-1}\), far larger than the on-going infrared-based SFR (\(~160\) M\(_{\odot}\) yr\(^{-1}\)) in the host galaxy.

\textsuperscript{†} Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.
Further mm CO-observations have now been done by our group in a number of the objects discussed here, finding similar CO outflows (Cicone et al. 2014). Remarkably, the CO outflow in Mrk 231 partially overlaps spatially and kinematically with blueshifted optical Na I D 5890, 5896 Å absorption features detected out to ∼2-3 kpc from the nucleus (Rupke, Veilleux, & Sanders 2005c). (3) Our high-resolution Gemini/IFU observations have revealed that the Na I D outflow in Mrk 231 is wide-angle, thus driven by a QSO wind rather than a jet (Rupke & Veilleux 2011, hereafter RV11). Similar wide-angle high-velocity outflows have now been mapped at high resolution in a number of other local ULIRGs (e.g., Rupke & Veilleux 2013a (RV13a) and Rupke & Veilleux 2013b). These powerful outflows may be the long-sought “smoking gun” of quasar mechanical feedback that clears out the molecular disk formed from dissipative collapse during the merger. The tentative trend of increasing OH terminal outflow velocity with increasing AGN luminosity identified by S11 adds support to this idea, but it is based on only 6 ULIRGs (and NGC 253, a regular starburst galaxy). To properly test this idea, one needs to examine a statistically representative sample of ULIRGs and study the properties of their molecular outflows uniformly and systematically. In Veilleux et al. 2013b (hereafter V13b), we report the first results from such a study, focusing on the directly measured outflow velocities. The sample consists of 43 objects, including 38 QUEST ULIRGs and 5 QUEST QSOs. All of these objects show signs of on-going or recent interactions. See V13b for a detailed discussion of the properties of the sample galaxies.

2. Results

The main results from this survey (V13b) are:

· The OH 119 μm feature was detected in 37 (86%) of the 43 sample galaxies.

· The nature of the OH 119 μm feature (emission, absorption, or both) depends on the properties of the galaxies: OH emission is stronger relative to OH absorption in quasar-dominated systems, becoming completely dominant (i.e. pure OH emission) in objects where the quasar contributes more than ∼90% to the bolometric luminosity (called the AGN fraction for short). This behavior is similar to that of the silicate 9.7 μm feature studied with Spitzer (Veilleux et al. 2009b) and the H I 21-cm feature measured with GBT in a subset of ULIRGs and QSOs (Teng et al. 2013).

· Unambiguous evidence for molecular outflows, based on the presence of absorption features with median velocities more blueshifted than −50 km s$^{-1}$, is seen in 26 (70%) of the 37 targets with detected OH 119 μm. Given possible projection effects, this wind detection rate is a lower limit and is consistent with all ULIRGs having molecular winds with an average opening angle ∼145°. In contrast, absorption features with median velocities above +50 km s$^{-1}$, indicative of inflow, are detected in only four objects, none of which show clear inverted P Cygni profiles. This result suggests that molecular inflows subtend a relatively small fraction of 4 π steradians (e.g., planar or filamentary geometry).

· Typical median outflow velocities are ∼−200 km s$^{-1}$, but terminal outflow velocities of ∼−1000 km s$^{-1}$ are detected in several objects. Deprojected outflow velocities will be even larger. The kinematics of these molecular outflows do not show any obvious dependence on the properties of the host galaxies (e.g., near-infrared derived stellar velocity dispersions, stellar masses) and star formation rates, although our sample covers a range of properties that is narrower than that of low-z non-molecular wind studies, where trends have been observed with these quantities.

· There is a tendency for objects with dominant and luminous AGN to show more blueshifted OH velocities (faster outflows; Figs. 1-2). Our data favor a steepening of the
Figure 1. The 50%, 84%, and terminal OH outflow velocities as a function of the AGN fractions. The meanings of the symbols are as follows: Filled black squares and filled red triangles represent ULIRGs with OH 119 μm seen purely in absorption and composite absorption/emission, respectively. The four objects with significant inflows (50% OH velocities above 50 km s\(^{-1}\)) are not shown here. Dotted lines indicate the best linear fits through the data. A significant linear correlation is present with \(v_{50}\) and \(v_{84}\) (P[null] \(\leq 0.05\)), but only tentatively with \(v_{\text{max}}\) (P[null] \(\sim 0.07\)). F12072--0444, indicated by an open red triangle, was not included in the evaluations of these correlations because it is not clear which of the two nuclei is responsible for the OH absorption feature (both nuclei are included in the PACS entrance aperture). Typical uncertainties on \(v_{50}\) and \(v_{84}\) are \(\pm 50\) km s\(^{-1}\) and \(\pm 200\) km s\(^{-1}\) on \(v_{\text{max}}\). The smaller symbols have larger uncertainties.
Figure 2. The 50%, 84%, and terminal OH outflow velocities as a function of the AGN luminosities. The meanings of the symbols are the same as in Figure 1. The four objects with significant inflows (50% OH velocities above 50 km s$^{-1}$) are not shown here. Dotted lines indicate the best linear fits through the data. A significant linear correlation is present with $v_{50}$ and $v_{84}$ ($P[\text{null}] \leq 0.05$), but only tentatively with $V_{\text{max}}$ ($P[\text{null}] \sim 0.09$). F12072–0444, indicated by an open red triangle, was not included in the evaluations of these correlations because it is not clear which of the two nuclei is responsible for the OH absorption feature (both nuclei are included in the PACS entrance aperture). Typical uncertainties on $v_{50}$ and $v_{84}$ are $\pm 50$ km s$^{-1}$ and $\pm 200$ km s$^{-1}$ on $V_{\text{max}}$. The smaller symbols have larger uncertainties.
relation between outflow velocities and the logarithms of the AGN luminosities above \( \log \left( \frac{L^{\text{break}}_{\text{AGN}}}{L_\odot} \right) = 11.8 \pm 0.3 \), although better statistics are needed, particularly at lower starburst and AGN luminosities, to confirm this non-linearity. While the trend between outflow velocities and AGN fractions may be explained as an obscuration effect, where both the AGN and central high-velocity outflowing material are more easily detectable when the dusty material has been swept away or is seen more nearly face-on, the dependence of the velocities on the AGN luminosities suggests that the AGN is playing a role in driving the fast winds. Our results emphasize that the use of the terminal velocities as the sole measures of outflow velocities should be avoided due to the much larger uncertainties on these measurements.

• The OH emission profiles in three of the four late-stage ULIRG/QSO mergers with AGN fractions above \( \sim 90\% \) are narrow, despite their large AGN luminosities, suggesting that the winds in these objects, if present, often have modest velocities. Quasar feedback thus seems to subside among mergers that have cleared a path through the dusty circumnuclear material.

3. Implications

The results from S11 on 6 ULIRGs in common with our sample indicate that the OH outflows are not only fast but also powerful, capable of displacing a significant fraction of the entire molecular ISM of the host galaxies. Given our methods of selection, there is no reason to believe that the objects studied here are any different from those in S11. Since the molecular ISM is the fuel for future star formation and galaxy build-up, the quasar-driven outflows detected here may therefore have a significant effect on the evolution of their hosts, potentially quenching star formation in their centers. The modest OH emission line widths in the infrared-faint quasars perhaps indicate that AGN feedback subsides once the quasar has poked a substantial hole through its natal “cocoon”, although this is based on only four objects.

There has been considerable theoretical support in recent years for the idea of quenching star formation in galaxies via AGN-driven winds (e.g., Narayanan et al. 2008; Hopkins et al. 2009 and references therein), but relatively little direct observational evidence for it, until recently (e.g., Feruglio et al. 2010; S11; RV11; RV13a). This last paper also points out the possibility of increasing outflow velocities at higher AGN luminosities. Using detailed IFU data on a sample of 6 ULIRGs, all from the QUEST sample, RV13a find that fast AGN-driven neutral (Na I D) and/or ionized (H\( \alpha \)) winds are only present in systems with \( \log \left( \frac{L^{\text{break}}_{\text{AGN}}}{L_\odot} \right) \geq 11.7 \). This AGN luminosity, while only tentatively identified in that paper since it is based on a very small sample, is consistent to within the uncertainties to that inferred from the larger set of Herschel data. This suggests that the conditions to drive fast neutral/ionized outflows are approximately the same as for the molecular outflows.

In this context, it is instructive to compare the OH velocities measured here with the Na I velocities measured by Rupke, Veilleux, & Sanders (2005a), Rupke, Veilleux, & Sanders (2005b), Rupke, Veilleux, & Sanders (2005c), and Krug et al. (2014, in prep.) from integrated spectra and RV13a from IFU data (Figure 13 of V13b). Also shown in this figure for comparison are the mid-infrared fine-structure line outflow velocities deduced by Spoon & Holt (2009) from Spitzer integrated spectra, the H\( \alpha \) velocities measured by RV13a from the IFU data, and the H I 21-cm velocities measured by Teng, Veilleux, & Baker (2013) from GBT integrated spectra. While the various velocities are measured over different scale (\( \lesssim 200 \) pc for the OH velocities according to S11 and \( \lesssim 1-2 \) kpc for the neutral and ionized gas velocities), general trends are observed: The outflow velocities of
the molecular gas are often comparable to the velocities of the neutral gas, but they are
generally smaller (more positive) than the velocities of the ionized gas (panels b and c
in Figure 13 of V13b). The similarity between the OH and Na I velocities is particularly
evident in panel (b) of Figure 13 of V13b where the sometimes very large nuclear Na I
and Hα outflow velocities, produced on sub-pc scale (e.g., Mrk 231; Veilleux et al. 2013a;
Figure 13a of V13b), are excluded from the means. This panel also reiterates the result
found by RV13a that the ionized gas is often, but not always, the fastest component of
the outflow. While dust obscuration may explain some of these variations (especially for
the highly ionized gas found near the center of AGN-dominated ULIRGs; e.g., blue wings
in [Ne V] emission profiles of Spoon & Holt 2009), it likely does not explain all of the
spatial variations found in the IFU data.

These multi-phase comparisons may help constrain the processes involved in acceler-ating the material entrained in the wind. In most cases, the acceleration \( a = F/m \) is
expected to depend strongly on the ISM phase. For instance, in the case of ram pressure
acceleration of clouds in a fast wind or a jet (e.g., Strel’nikskii & Sunyaev 1973; Cheva-
lier & Clegg 1985), the force on a spherical cloud of mass \( M_{\text{cloud}} \) and density \( \rho_{\text{cloud}} \) is
expected to scale as the area of the cloud or \( (M_{\text{cloud}}/\rho_{\text{cloud}})^{2/3} \) and thus we expect the
acceleration to scale as \( (M_{\text{cloud}}\rho_{\text{cloud}}^{2})^{-1/3} \) (we neglect gravity). Naively, one would ex-
pect the molecular clouds to be considerably denser and more massive, on average, than
the ionized gas clouds so one would expect the molecular material to always move at
lower velocities. This simple-minded argument may be relaxed if each accelerated cloud
has a multi-phase structure (e.g., ionized skin or halo surrounding a neutral/molecular
core) and thus contributes all at once to the molecular, neutral, and ionized phases of
the outflow. But the significant difference in velocities often seen between the ionized
and molecular gas phases (Figure 13 of V13b) indicates that this situation cannot ap-
ply to the bulk of the outflowing material since the difference in velocities between the
various phases would imply severe shearing/shredding and very short cloud lifetimes
\( \sim R_{\text{cloud}}/\Delta v \sim 10^{4} (R_{\text{cloud}}/\text{pc})(100 \text{ km s}^{-1}/\Delta v) \) years, where \( R_{\text{cloud}} \) is the cloud radius
and \( \Delta v \) is the difference in velocities between the various gas phases.

Another possible source of acceleration for these winds is UV-IR radiation pressure.
It has the distinct characteristic to be less efficient at accelerating ionized material than
dusty neutral/molecular material due to the different sources of opacity. Within the dust
sublimation radius, \( R_{\text{subl}} \sim L_{46}^{1/2} \) pc (where a dust sublimation temperature \( T_{\text{subl}} \sim 1200 \)
K was assumed), the dominant source of opacity is electron scattering and the corre-
sponding luminosity condition to drive a (spherical) wind is the well-known Edding-
ton luminosity. Estimates of the black hole masses \( M_{\text{BH}} \) in our sample galaxies range
from \( \sim 0.5 – 5 \times 10^{8} M_{\odot} \) (e.g., Vestergaard & Peterson 2006; Veilleux, Kim, & Sanders
2002; Veilleux et al. 2009a), corresponding to Eddington luminosities \( L_{\text{Edd}} = 1.3 \times 10^{46}
(M_{\text{BH}}/10^{8}) = 0.65 – 6.5 \times 10^{46} \text{ ergs s}^{-1} \). Systems near the AGN luminosity break iden-
tified in our data are therefore accreting at sub-Eddington values \( \Gamma \equiv L_{\text{AGN}}/L_{\text{Edd}} \sim 0.04 – 0.4 \).

Outside the dust sublimation radius, the much larger dust opacity prevails and UV-IR
radiation pressure from the AGN may drive significant winds. In this situation where
dust opacity dominates, Murray, Quataert, & Thompson (2005) have derived a handy
expression for the limiting, Eddington-like luminosity above which momentum deposition
from the quasar (and/or starburst) is presumed to be enough to clear most of the gas
out of galactic nuclei (i.e. this is a criterion to “blow away” the gas rather than just a
“blow out” in the nomenclature of De Young & Heckman 1994):

\[
L_{M} \sim (4f_{g}c/G)\sigma^{4} \sim 3 \times 10^{46} (f_{g}/0.1)(\sigma/200 \text{ km s}^{-1})^{4} \text{ ergs s}^{-1},
\]
where $f_g$ is the gas fraction of the host and $\sigma$ is the stellar velocity dispersion, a measure of the depth of the gravitational potential well. In our sample galaxies, $f_g \approx 0.1$ on average, although there is considerable scatter among ULIRGs (e.g., Downes & Solomon 1998; Combes et al. 2013 and references therein), while $\sigma$ ranges from $\sim$120 to $\sim$280 km s$^{-1}$ with an average value of $\sim$200 km s$^{-1}$ (as mentioned in §4.4 of V13b, this value can be considered a lower limit, Rothberg & Fischer 2010; Rothberg et al. 2013). The steep dependence of $L_M$ on $\sigma$ implies that $L^\text{break}_{\text{AGN}} \approx 2 – 100%$ of $L_M$, with an average value of $\sim 10\%$, i.e. the AGN luminosity break above which the AGN plays a dominant role in driving the outflowing molecular gas in local ULIRGs is generally lower than the Eddington-like luminosity derived by Murray et al. (2005). The fact that $L^\text{break}_{\text{AGN}}$ is lower than $L_M$ is not surprising since the latter quantity is the maximum luminosity an object may have before blowing away all of the gas from a galaxy via radiation pressure on dust. For more details, see V13b.
