Abstract
N-acetyl cysteine (NAC) has been widely used for preventing reactive oxygen species-induced damage. However, little is known as to whether dietary NAC supplementation would alleviate intestinal injury in weaned piglets. The present study evaluated the effect of NAC on enterocyte apoptosis and intracellular signalling pathways’ response to weaning stress. The control piglets were normally suckling, and piglets in the weaning and NAC groups were fed the basal diet and basal + NAC diet from 14 to 25 d of age, respectively. Compared with the control piglets, weaning increased cortisol concentrations (P<0.05), decreased superoxide dismutase and glutathione peroxidase activities (P<0.05), increased malondialdehyde content (P<0.05) in serum and enhanced enterocyte apoptosis index (AI) and concentrations of caspase-3, caspase-8 and caspase-9 (P<0.05). Gene expression analyses indicated that weaning induced apoptosis via Fas signalling and mitochondrial pathways in weaned piglets. Dietary NAC supplementation decreased (P<0.05) cortisol concentrations and the AI, increased (P<0.05) antioxidant status in serum and alleviated histopathological changes in the intestine. It also inhibited Fas, caspase-3, caspase-8 and integrin αvβ6 (αvβ6) gene expressions in the NAC-treated piglets. However, no significant decrease (P>0.10) in caspase-3, caspase-8 and caspase-9 concentrations was observed in the NAC group compared with the weaning group. In conclusion, weaning may induce enterocyte apoptosis via the activation of Fas-dependent and mitochondria-dependent apoptosis. Although NAC had no effect on caspase concentrations, it was clearly beneficial for preserving morphological integrity in weaned piglets via the regulation of cell apoptosis and the inhibition of Fas-dependent apoptosis and αvβ6 expression.

Key words: Piglets: Intestinal morphology; N-acetyl-L-cysteine: Apoptosis

Apoptosis is thought to be essential for epithelial turnover in intestinal mucosa and tissue homeostasis in intestinal epithelium. Abnormal apoptosis would result in intestinal mucosal barrier damage and gastrointestinal disorders(1). In swine production, weaning is a critical process for piglets due to dramatic changes in diets and environment. The obvious intestinal morphological changes induced by weaning stress are villous shedding, villous shortening and crypt hyperplasia(2). Indeed, reactive oxygen species (ROS)-induced apoptosis has been widely studied, which is also an important mechanism for many chemotherapeutic agents. Oxidative stress results from the overproduction of ROS, which are also known as mediators of damage to cell structures, including lipids and membranes, proteins and DNA(3). The effect of ROS is balanced by the antioxidant action of antioxidant enzymes as well as non-enzymatic antioxidants. The most efficient enzymatic antioxidants include superoxide dismutase (SOD), glutathione peroxidase (GSH-Px) and catalase(4). Non-enzymatic antioxidants are represented by vitamin C, vitamin E, glutathione (GSH) and so on(5). Reducing oxidative stress by supplementation of non-enzymatic antioxidants, such as L-arginine(6), GSH (7) and vitamin C(8), could potentially reduce ROS-induced damage and inhibit apoptosis.

We have demonstrated previously that weaning increases the concentrations of NO and H2O2 in serum in post-weaning piglets and that feeding an antioxidant-containing diet could prevent free radical-induced damage and suppress oxidative stress(9). However, the relationships among weaning-induced free radical generation, apoptosis and intestinal mucosal damage are still unclear in pigs. Therefore, elucidation of the mechanisms of weaning-induced apoptosis might help in...

understanding the physiological regulation of the apoptotic process in pig intestinal mucosa.

GSH, responsible for the detoxification of ROS, is the primary metabolic precursor for intestinal epithelial cells. Intracellular GSH depletion induces chromosomal DNA fragmentation, which is associated with apoptosis and necrosis. Glutamine administration can protect against gut injury, and one of the possible ways of action is related to the preservation of GSH content. \( \text{N-acetyl cysteine (NAC), a well-known thiol antioxidant and GSH precursor, has been demonstrated to be beneficial for preventing ROS-induced damages.} \) Recently, it has been proved that NAC prevents exercise-induced intestinal lymphocyte apoptosis by maintaining intracellular GSH contents and reducing mitochondrial membrane depolarisation. Administration of NAC before ischaemia in experiments was effective in the prevention of bacterial translocation and oxidative stress. Moreover, NAC is a clinically proven safe dietary supplement that may be useful in clinical therapy for ROS-mediated diseases. These beneficial properties of NAC suggest that it may be considered as a useful additive to diets for the prevention of weaning stress.

In the present study, we attempted to characterise the relationship between apoptosis and intestinal mucosal damage induced by weaning in piglets. We also aimed to investigate whether NAC can effectively prevent weaning-induced intestinal damage in piglets. Particular attention was afforded to changes in serum antioxidant activities, intestinal morphology, and enterocyte apoptosis and functions in an attempt to identify any intracellular signalling changes regulated by weaning and NAC treatment. To our knowledge, this is the first study in piglets to simultaneously evaluate weaning-induced apoptosis and the potential wound-healing function of NAC through the regulation of cell apoptosis in response to weaning stress.

**Materials and methods**

**Animals and experiment design**

The experiment was approved by the Shanghai Jiaotong University Institutional Animal Care and Use Committee. A total of 150 14-d-old piglets (Duroc × Landrace) were randomly divided by litter into control, weaning and NAC groups with five litters per group. The piglets were kept with the sow in conventional farrowing pens and suckled until 21 d of age. From 14 to 25 d of age, piglets in the control and weaning groups had ad libitum access to the basal diet and the NAC-treated piglets were fed the basal diet supplemented with 500 mg/kg of NAC. The dosage of supplemental NAC was chosen based on the study by Hou et al. with 35-d-old piglets. Dietary ingredients, analysed energy and nutrient contents of the basal diets (as-fed basis) with 14-48 MJ/kg digestible energy and 20-50% crude protein (N × 6.25) have been described previously. At 21 d of age, piglets of the weaning and NAC groups were weaned and moved from the farrowing pens to nursery pens without mixing any litters. The control piglets were retained in the farrowing pens to suckle until the 25 d experiment. Temperature in the farrowing and nursery pens was maintained at about 30°C.

**Sample collection**

At 25 d of age, three piglets from each litter, resulting in a total of fifteen piglets per treatment, were selected and blood samples were collected from the anterior vena cava. The selected piglets had a body weight that was close to the average for the litter. Serum was separated by centrifugation at 3500 g for 15 min at 4°C and stored at −20°C until analysis for cortisol and antioxidative physiological measures. One piglet was randomly chosen from each litter, resulting in a total of five piglets per treatment. The piglets were anaesthetised by intramuscular injection of sodium pentobarbital (50 mg/kg body weight) and then euthanised, and gut samples were collected. The entire small intestine was carefully removed and placed on ice. Some pieces, approximately 2 cm in length, were resected from the middle portion of the jejunum and fixed in 4% neutral buffered formalin for the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labelling (TUNEL) assay. In addition, some specimens of jejunum sections were fixed for 15 min at 4°C and stored at −70°C. Half of the specimens were used for the evaluation of apoptotic proteins with ELISA and the remaining half were used for quantitative RT-PCR analyses.

**Serum cortisol content**

Serum concentrations of cortisol were quantified using a Coat-A-Count Cortisol kit (Diagnostic Product Corporation) according to the manufacturer’s protocol. Unknown concentrations were compared against the cortisol kit standard and expressed as µg/l of cortisol. This value was then converted and expressed as ng/ml of cortisol. The optical density at 450 nm was measured after colouration. All assays were performed in duplicate. The minimum detection limit was 7 ng/ml, and the use of the cortisol kits for porcine samples has been validated.

**Antioxidative physiological analyses**

The activities of SOD and GSH-Px and the content of malondialdehyde (MDA) in serum were determined to evaluate the antioxidant ability and lipid peroxidation in pigs, using assay kits according to the manufacturer’s instructions (Nanjing Jiancheng Bioengineering Institute). In brief, the activity of total SOD was determined by monitoring the inhibition of nitro blue tetrazolium reduction. One unit of SOD activity was defined as the amount that reduced the absorbance at 550 nm by 50% in 1 ml serum, and data were expressed as...
units/ml serum. The activity of GSH-Px was determined by measuring the reduction of GSH per min on the basis of its catalysis. The final result was expressed as a decrease of 1 μmol/l of GSH per 5 min for 0·1 ml serum at 37°C after the subtraction of the non-enzymatic reaction, and data were expressed as units/ml serum and then converted to units/μl. MDA content was analysed with 2-thiobarbituric acid, and data were expressed as nmol/ml serum. All absorbance levels were measured using a UV–visible spectrophotometer (Tongfang, Inc.).

Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labelling staining

Jejunum samples, fixed in 4% neutral buffered formalin, were embedded in paraffin and sectioned. The specimens were stained with haematoxylin and eosin for histological examination. Mucosal length (villus height plus crypt depth) was calculated using the TUNEL assay method with some modifications using a FragELTM DNA Fragmentation Detection Kit (Merck). In brief, the specimens were de-waxed and incubated with 20 μg/ml proteinase K for 20 min at room temperature and then reacted with the terminal deoxynucleotidyl transferase enzyme for 60 min at 37°C. The specimens were then incubated with anti-digoxigenin peroxidase at room temperature for 30 min followed by a thorough washing with PBS. Finally, the specimens were incubated with diamino-benzidine solution and counterstained with methyl green. A minimum of twenty crypts were randomly selected for apoptotic index analysis, and the number of apoptotic cells was calculated. The apoptotic index was determined by dividing the number of apoptotic cells by the total number of cells in the crypt column and multiplying by 100.

Specimen preparation for electron microscopy

Mucosal specimens of jejunum sections were fixed with 2.5% glutaraldehyde in 0·1 mol/l cacodylate buffer (pH 7·2) for 2 h at 4°C. These specimens were then washed three times with the same buffer and post-fixed with osmium tetroxide for 2·5 h at 4°C. They were later washed with 0·1% sodium acetate, stained with 1% uranyl acetate, dehydrated with ethanol and embedded in Spurr's low-viscosity resin. Representative areas were sectioned and stained with toluidine blue. Ultrathin sections were prepared and double stained with uranium and lead. A Hitachi H-600 transmission electron microscope (Hitachi) was used to visualise the ultrastructure of the enterocytes and the distribution of epithelial cell microvilli.

Concentrations of caspase in the jejunum

Relative amounts of caspase-3, caspase-8 and caspase-9 in the homogenates of the jejunum of the selected piglets were determined using specific ELISA kits (R&D Systems, Inc.) according to the manufacturer’s instructions. Each individual sample was analysed in triplicate. In brief, individual jejunum samples were homogenised in ten volumes of PBS (pH 7·0) on ice and centrifuged at 3000g for 15 min. The supernatant was decanted and stored. Protein concentrations in the supernatant were determined using a BCA protein assay kit (Pierce). Caspase concentrations were determined using a spectrophotometer (450 nm) on a microtitre plate reader.

Quantitative RT-PCR

Total RNA was extracted from jejunal tissues using TRIzol reagent (Invitrogen) following the manufacturer’s instructions and purified using DNase I (Invitrogen) for 15 min. The yield

ACTB, β-actin; F, forward primer; R, reverse primer; GAPDH, glyceraldehyde 3-phosphate dehydrogenase; B2M, β-2-microglobulin; Bax, B-cell lymphoma-2-associated X protein; Bcl-2, B-cell lymphoma-2; αvβ6, integrin αvβ6.
and quality of RNA were assessed using a spectrophotometer (Bio-Rad Laboratories, GmbH), considering the ideal absorbance ratio (1.8 ≤ A260/280 ≤ 2.0). The integrity of RNA was checked by electrophoresis on a 1.5% agarose gel. A volume equivalent to 1 μg of total RNA was reverse-transcribed using random primers according to the manufacturer’s protocol (TaKaRa). The resulting complementary DNA was diluted and used as a PCR template to evaluate gene expression. Quantitative RT-PCR was conducted on an Eppendorf Mastercycler ep Realplex Real-Time Quantitative PCR System (Eppendorf) using SYBR Premix Ex Taq™ kits (TaKaRa) under the following conditions: pre-denaturation at 95°C for 30 s and forty cycles of 95°C for 5 s, 60°C for 30 s and 72°C for 15 s. A dissociation curve was constructed at the end of the reaction to ensure that only one amplicon was formed. Primers for the genes of interest were designed based on the pig (Sus scrofa) sequence (Table 1) using primer design software (Primer Premier 5.0; PREMIER Biosoft International). Amplification efficiencies were calculated based on the slope of the line (E = 10\(^{(-1/slope)}\) – 1), considering an ideal value range (0.95 ≤ E ≤ 1.05). All experiments were repeated in triplicate. The geometric means of the relative abundances were normalised against porcine β-actin, glyceraldehyde 3-phosphate dehydrogenase and β-2-microglobulin genes using the 2\(-ΔΔCt\) method (21). Relative gene expressions in the weaned and NAC-treated piglets represented the comparison v: suckling piglets and were reported as a fold change from the value of the suckling piglets.

Statistical analyses
All data are presented as means with their standard errors. Differences among the examined groups were determined using one-way ANOVA followed by Tukey’s test. Values with \( P < 0.05 \) were considered as statistically significant. Trends were reported when 0.10 < \( P < 0.05 \).

Results

Serum cortisol content

As shown in Fig. 1, cortisol concentrations in piglets of the control, weaning and N-acetyl cysteine (NAC) groups at 25 d of age. Values are means, with their standard errors represented by vertical bars. Mean values with unlike letters were significantly different (\( P < 0.05 \)). Control group (a), piglets suckled from 14 to 25 d of age. Weaning group (b), piglets weaned at 21 d of age and fed the basal diet. NAC group (c), piglets weaned at 21 d of age and fed the basal diet supplemented with 500 mg/kg of NAC.

Oxidative stress induced by weaning

The activities of SOD and GSH-Px and the content of MDA in serum are presented in Table 2. The activities of GSH-Px in serum were significantly lower (\( P < 0.05 \)) in the weaned piglets than in the control piglets. The activities of SOD also showed a trend to be lower (\( P = 0.055 \)) in the weaning group compared with the control group. The content of MDA, the product of lipid peroxidation, was significantly increased (\( P < 0.05 \)) in the piglets of the weaning group compared with those of the control group. Supplementing the diet with NAC increased the activities of SOD and GSH-Px (\( P < 0.05 \)) compared with the weaning group and lessened (\( P < 0.05 \)) the MDA content to levels that were not different from those observed in the control piglets.

Light microscopy findings

Representative histological graphs of haematoxylin and eosin-stained intestine samples of the control, weaning and NAC groups are shown in Fig. 2(E). The control specimens showed normal and typical leaf-like villus crypts. In contrast, villus height in the jejunum was significantly decreased (\( P < 0.05 \)) in the weaning group, whereas villus width showed a small decrease (\( P < 0.05 \)) in the weaned piglets.

Table 2. Serum superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px) activities and malondialdehyde (MDA) content in piglets of the control, weaning and N-acetyl cysteine (NAC) groups at 25 d of age

| Items                  | Control\( ^* \) | Weaning\( ^† \) | NAC\( ^‡ \) | Pooled SE
|------------------------|-----------------|-----------------|-------------|---------------------
| SOD (units/ml serum)   | 72.23\( ^a \)   | 47.79\( ^b \)   | 98.36\( ^a \) | 13.61
| MDA (mmol/ml serum)    | 4.52\( ^a \)    | 7.08\( ^a \)    | 4.58\( ^b \)  | 0.964
| GSH-Px (units/μl serum)| 1.28\( ^a \)    | 0.56\( ^b \)    | 1.27\( ^a \)  | 0.185

\(^a,b,c\) Mean values within a row with unlike superscript letters were significantly different (\( P < 0.05 \)).
\(^\ast\) Piglets suckled from 14 to 25 d of age.
\(^\dagger\) Piglets weaned at 21 d of age and fed the basal diet.
\(^\ddagger\) Piglets weaned at 21 d of age and fed the basal diet supplemented with 500 mg/kg of NAC.
\(^\S\) One unit of SOD activity was defined as the amount required to inhibit the reduction in nitro blue tetrazolium by 50% of maximum inhibition in 1 ml serum.
\(^\‡\) One unit of GSH-Px activity was defined as a decrease of 1 μmol of GSH per 5 min for 0.1 ml serum at 37°C after subtraction of the non-enzymatic reaction.
relative to the control piglets. In addition, the weaned piglets showed larger crypt depths ($P<0.05$) than the control piglets. Feeding the NAC-containing diet increased ($P<0.05$) villus height and villus width ($P<0.05$) and decreased the crypt depths ($P<0.05$) in the jejunum compared with the weaned piglets. The increased number of apoptotic cells (apoptotic nuclei are stained dark brown) with significant localisation of apoptotic cells in the upper tip of the intestinal villi (Fig. 2(A)–(C)) was revealed by the TUNEL assay in the weaned piglets. Moreover, the apoptotic index was higher in the weaned piglets ($P<0.05$) than in the control piglets (Fig. 2(D)). A few apoptotic cells were present at the villus tips in the jejunum of the NAC group, and the apoptotic index ($P<0.05$) in the piglets fed the NAC diet was decreased compared with those of the weaning group.

**Electron microscopy findings**

Electron microscopic examination of the jejunal mucosa is shown in Fig. 3. In the weaning group, some enterocytes showed necrotic injuries characterised by serious damage to the plasma membrane, complete loss of junction specialisations between adjacent cells and swollen mitochondria without crests. Some other detached cells had characteristic features of apoptosis with vacuolated cytoplasm, cell compaction, condensed chromatin and fragmented mitochondria. No apoptotic features were found in the intestinal epithelia of the
control group except severe chromatin agglutination and mitochondrial ridge damage. The microvilli were well developed in the control piglets. In the NAC group, the microvilli were well developed, and the enterocyte ultrastructure was similar to that of the control group.

**ELISA for caspase content**

As shown in Table 3, the concentrations of caspase-3, caspase-8 and caspase-9 were strongly increased \((P<0.05)\) in the jejunum of the weaned piglets when compared with the control piglets, showing an increased apoptosis due to the weaning treatment. The concentrations of caspase-3 and caspase-9 tended to decrease \((P=0.092\) and \(P=0.075\)) in the NAC-treated group compared with the weaning group. Compared with the control piglets, concentrations of caspase-3, caspase-8 and caspase-9 were still strongly increased \((P<0.05)\) after the NAC-containing diet treatment.

**Quantitative RT-PCR analysis of apoptosis genes**

Results for quantitative RT-PCR analysis are shown in Fig. 4. A significant increase \((P<0.05)\) in caspase-3, caspase-8, Fas and integrin \(\alpha v\beta 6\) \((\alpha v\beta 6)\) expressions was observed in the weaned
piglets compared with the control piglets. No significant
differences in the pro-apoptotic factor B-cell lymphoma-2
(\textit{Bcl-2})-associated X protein and \textit{caspase-9} expressions
\((P>0.10)\) were observed among the three groups, while
weaning decreased \((P<0.05)\) the expression of the anti-
apoptotic factor \textit{Bcl-2} in the weaned piglets compared with
the control piglets. The NAC-containing diet decreased
\((P<0.05)\) the expressions of \textit{caspase-3}, \textit{caspase-8}, \textit{av\textbeta 6}
and \textit{Fas} compared with the weaning group. Compared with
the weaning group, the expression of \textit{Bcl-2} was increased
\((P<0.05)\) in the NAC group.

Discussion

Cortisol is the primary glucocorticoid released during stress,
which is normally increased for at least the first 24 h post-
weaning in pigs, revealing the occurrence of a stress
response\((22,23)\). Antioxidant supplementation is able to decrease
cortisol concentrations under stress\((22,23)\). In the present study,
the increased cortisol concentrations after weaning suggest
that the piglets experienced stress at weaning. NAC, a
well-known antioxidant\((14)\), tended to decrease cortisol con-
centrations after weaning, indicating that it has the potential
to counteract weaning stress.

Stress, especially oxidant stress, that is caused by reactive
nitrogen species and/or ROS is known to play a major role
in the pathogenesis of tissue injury in many diseases, and
the removal of free radicals may offer a treatment choice.
SOD enzymes, as the major cellular antioxidants, can directly
scavenge the excessive free radicals such as OH\textsuperscript{−}, \textit{H}_2\textit{O}_2 and
\textit{O}_2\textsuperscript{−} by working in conjunction with other \textit{H}_2\textit{O}_2-removing
enzymes, such as GSH-Px\((24)\). GSH, a potent endogenous anti-
oxidant, is a first line of defence against free radicals and is
often depleted as a consequence of the increased status of
oxidative stress and inflammation\((11)\). Lipid peroxidation, a
free radical-related process, is a chain reaction leading to the
oxidation of fatty acids, disrupting membrane structure and
producing toxic metabolites such as MDA\((25)\). In the present
study, we observed higher lipid peroxidation and reduced
SOD and GSH-Px activities in the weaned piglets compared
with the control piglets, which is in agreement with previous
findings in intestinal ischaemia–reperfusion injury in rats\((26)\).
We also demonstrated that weaning induced free radical
generation, including NO and \textit{H}_2\textit{O}_2, and decreased \textit{O}_2
concentrations in serum\((9)\). Hence, in response to the increased
production of free radicals after weaning, antioxidant enzymes
(SOD and GSH-Px) may be broken down by free radicals. In
addition, studies have reported that NAC has protective effects
on the occurrence of oxidative stress resulting from ischae-
media–reperfusion by preventing MDA, SOD and GSH-Px
changes in animal models\((27,28)\). As a potent antioxidant,
NAC directly scavenges \textit{H}_2\textit{O}_2, OH\textsuperscript{−} and hypochloric acid \textit{in vitro}\((29)\)
and exerts antioxidative effects by facilitating the

\end{figure}
generation of intracellular antioxidants, such as GSH\textsuperscript{(30)}. In the present study, administration of the NAC-containing diet to the weaned piglets significantly reduced lipid peroxidation and restored the SOD and GSH-Px activities to near-control levels; this is probably because of its free radical-scavenging activity or endogenous synthesis of GSH by NAC\textsuperscript{(29,30)}. The high SOD activities in the NAC-treated piglets than in the control piglets might be due to the restoration of GSH by NAC and the early NAC supplementation for 12 d (from 14 to 25 d of age). It could be that the increased SOD and GSH-Px activities in serum may reflect the up-regulation of the antioxidant defence system in response to weaning stress in the NAC-treated piglets. These results suggest that NAC may have a protective effect on oxidative stress resulting from weaning in the piglet models.

As apoptosis plays a crucial role in free radical-induced gastrointestinal damage\textsuperscript{(31-32)}, we examined enterocyte apoptosis and histopathological changes in the intestine in response to weaning stress and determined whether NAC supplementation could improve the integrity of intestinal mucosa in weaned piglets. Confirmation of apoptosis was based on the findings obtained from both morphological and biochemical measurements. The TUNEL assay and ELISA procedure confirmed an increased apoptosis in the intestinal mucosa of the weaned piglets. However, cell death occurs by two distinctly different pathways: programmed cell death (apoptosis) or necrosis\textsuperscript{(33)}. In the present study, transmission electron microscopy was used to distinguish apoptosis and necrosis, since necrosis is associated with histological signs of inflammation, whereas apoptosis is not. In the present study, concurrent necrosis and apoptosis were observed in the jejunum of the weaned piglets. These data provide an explanation for the clinical observation that piglets that are weaned tend to develop intestinal inflammation easily\textsuperscript{(34)}. This would also explain why there is an increase of pro-inflammatory cytokines in the intestine of the weaned piglets\textsuperscript{(32)}. In the present study, we observed that an increase in Fas, caspase-8 and caspase-3 expressions coincided with decreases in the GSH-Px and SOD activities in the weaned piglets, and these were reversed by the NAC-containing diet. These results suggest that the ability of NAC to inhibit cell death in the weaned piglets might be more inclined to decrease apoptosis via Fas-dependent apoptosis.

Integrin αvβ6 is a well-known cell surface receptor and is not expressed constitutively by healthy adult epithelial cells, but is rapidly enhanced upon stimulation such as cell injury, cancer and inflammation, and its expression is maintained until wound closure is complete\textsuperscript{(42)}. High expression of αvβ6 in colon cancer is associated with a more aggressive disease outcome, leading to the spread and development of cancer\textsuperscript{(43)}. In the present study, we showed a dramatic increase in the expression of αvβ6 in the weaned piglets, which is consistent with the previous studies of gut challenged with nematodes\textsuperscript{(44)}. The high expression of αvβ6 in the weaned piglets might provide an explanation for the clinical observation that weaned piglets with small-intestinal inflammation tend to have worse outcomes than diarrhoea\textsuperscript{(45)}. Furthermore, on blocking the function of αvβ6 in colon cancer cells, apoptosis is enhanced and signalling involves the mitochondrial pathways\textsuperscript{(46)}. Enhanced mitochondrial ROS production is classically reported during cell apoptosis. Mitochondrial dysfunction promotes cancer cell migration through the induction of integrin αvβ5 via an increase in mitochondrial-generated ROS\textsuperscript{(47)}. In the case of weaned piglets, damage of the intestinal epithelium has been observed due to weaning stress via enhanced free radical generation\textsuperscript{(49)}. Hence, we think that the increased apoptosis in the weaned piglets is associated with the expression of αvβ6. Additionally, αvβ6 is up-regulated during tissue remodelling, which occurs in epithelial repair as well as in cancer, but the timing and topology of the expression of αvβ6 are important for normal repair\textsuperscript{(48)}. Partial inhibition of αvβ6 may prevent pulmonary fibrosis without exacerbating inflammation\textsuperscript{(49)}. Here, the down-regulated expression of αvβ6 in the NAC-treated piglets might indicate that the potential wound-healing function stimulated by NAC might be associated with the regulation of αvβ6. However, the expression of αvβ6 was still higher than that in the control piglets, as well as high caspase-3, caspase-8 and caspase-9 concentrations were induced in epithelial cell apoptosis following the weaning treatment. The expressions of caspase-3, caspase-8, Bcl-2 and Fas were reversed by the NAC-containing diet treatment. Thus, it appears that the caspase-3, caspase-8, Bcl-2 and Fas genes may be regulated via redox-sensitive mechanisms in intestinal epithelial cells. However, no significant effect was observed on the expressions of Bcl-2 associated X protein and caspase-9 in the NAC-treated piglets. This likely reflects the prolonged kinetics of apoptosis in epithelial cells. In addition, the intrinsic pathway is essential for the ROS-mediated apoptosis\textsuperscript{(39)}, but is not exclusive to this death pathway. In fact, ROS-mediated apoptosis is shared between mitochondria-dependent apoptosis and Fas-dependent apoptosis\textsuperscript{(15,39)}. Evidence has proved that ROS scavengers, such as GSH, NAC and SOD, can cause the inhibition of Fas-induced apoptosis in different cell types\textsuperscript{(15,40,41)}. In the present study, we observed that an increase in Fas, caspase-8 and caspase-3 expressions coincided with decreases in the GSH-Px and SOD activities in the weaned piglets, and these were reversed by the NAC-containing diet. These results suggest that the ability of NAC to inhibit cell death in the weaned piglets might be more inclined to decrease apoptosis via Fas-dependent apoptosis.
observed using the ELISA method. These data may reflect that further studies should be conducted to more completely determine the optimal dosage and time of NAC.

In conclusion, weaning could increase enterocyte apoptosis by activating both the intrinsic and extrinsic apoptotic pathways in post-weaning piglets. The NAC-containing diet used in the present study could preserve the morphological integrity of intestinal mucosa and inhibit cell death by reducing apoptosis via Fas-dependent apoptosis and αβ6 expression in weaned piglets. The signalling mechanisms still remain to be elucidated.
