Sintering describes the consolidation of individual (nano) particles to form a dense microstructure through the application of heat, pressure, electric fields, etc. [1] Electric field-assisted sintering (EFAS) is a type of sintering technique with a large number of studies reported in the literature and wide application. In fact, sintering studies of various oxide materials at low temperatures has been done however not much have been devoted on consolidation of iron oxide [2]. In both cases, the atomic scale consolidation mechanisms under heating rates and electrical fields during EFAS remain mostly unclear [3].

Iron oxide (γ-Fe₂O₃) nanoparticles with size ranging from 5 to 50 nm in diameters were synthesized using a modified H₂/air diffusion flame configuration [4]. Nanochains of the particles were produced by the applied magnetic field acting perpendicular to the flame direction. These particles were collected 55 mm above the visible flame by rapidly inserting the Aduro MEMS heating device. JEOL JEM 2500SE transmission electron microscope (TEM) and an aberration corrected JEOL JEM 2100F/Scanning transmission electron microscope (STEM) with a Gatan Tridiem parallel electron energy loss spectrometer operated at 200 KV were used for the in situ heating studies. With a Protochips Aduro heating holder, temperatures from 200°C to 900°C with 50°C increments for 200 s were applied. TEM/STEM images and video signals were acquired while electron energy loss spectra (EELS) were recorded in between each heating cycle. The oxidation state of iron oxide particles during annealing was quantified by calculating the Fe L₃/L₂ intensity ratio using the quantification method by Jacinski et al. [5].

Figure 1 shows the high angle annular darkfield (HAADF) images of the iron oxide nanochains at 400°C (Figure 1a) and 500 °C (Figure 1b), respectively. Neck formation between the particles and subsequent growth was observed (see Figure 1b). Further application of temperature led to rapid consolidation of the nanochains at 900°C [6]. EELS measurements and quantification of the Fe L₂,₃ ionization edges (Figure 2) revealed a phase transition from γ-Fe₂O₃, Fe₃O₄, FeO and finally to Fe which was attributed to oxidation-reduction reactions during annealing [6]. In fact, the shift in Fe L₃ from 600°C- 900°C (oxide to metal in Figure 2) of 1.4 eV correlated to FeO-Fe chemical shift of EELS Fe L₃ edge by Leapman et al. [7]. In this case, the iron oxide reduction from Fe₂O₃ to Fe was driven by the increasing annealing temperature resulting to increased surface diffusion for sintering starting from 400 °C. Thus, a preferred phase of Fe₃O₄ for sintering during the in situ study was identified. The results from this study provided evidence for reduction-oxidation reaction mechanisms during sintering. Furthermore, the in situ heating experiment provided valuable information on sintering of fully oxidized nanometric material such as iron oxide [8].
