Abstract
A higher fat content in the diet could be an advantage for preventing malnutrition among older adults. However, there is sparse scientific evidence to determine the optimal fat intake among older adults. This prospective cohort study examined whether a high energy intake of dietary fat among middle-aged and older adults is associated with the risk of malnutrition 10 years later. The study population comprised 725 Swedish men and women aged 53–80 years who had completed a questionnaire about dietary intake and lifestyle factors in 1997 (baseline) and whose nutritional status was assessed when admitted to the hospital in 2008–2009 (follow-up). At the follow-up, 383 (52.8%) participants were identified as being at risk of malnutrition and fifty-two (7.2%) were identified as malnourished. Multinomial logistic regression models were used to analyse the association between previous dietary fat intake and nutritional status later in life. Contrary to what was expected, a high energy intake from total fat, saturated fat and monounsaturated fat among middle-aged and older adults increased the risk of exhibiting malnutrition 10 years later. However, this applied only to individuals with a BMI < 25 kg/m² at the baseline. In conclusion, these findings suggest that preventive actions to counteract malnutrition in older adults should focus on limiting the intake of total fat in the diet by reducing consumption of food with a high content of saturated and monounsaturated fat.

Key words: Cohort studies; Dietary fat; Epidemiology; Malnutrition; Mini Nutritional Assessment

Good dietary habits increase the likelihood of living a long and healthy life by preventing diet-related diseases(3). Studies of the relationship between previous dietary intake and future disease at an older age are therefore of value. During ageing, physiological changes and diseases increase the risk of a reduced appetite. As a consequence, protein–energy malnutrition (malnutrition) increases with ageing(2) and it affects a significant proportion of older adults(3,4). This condition is associated with greater health-care costs(5), worse quality of life(6) and preterm death(7). The identification of modifiable risk factors in the diet is thus desirable for taking preventive action before malnutrition develops.

A higher percentage of fat in the diet (energy percentage (E%)) is associated with a higher energy intake (kJ (kcal)) and a higher body weight(8). The biological reason to this is that energy-dense foods are often palatable and associated with a decreased satiation, which leads to passive over-consumption(8,9). Dietary fat is the most energy-dense nutrient (37-1 kJ/g (9 kcal/g)), as opposed to carbohydrates (16-7 kJ/g (4 kcal/g)) and proteins (16-7 kJ/g (4 kcal/g)). Consequently, most foods that have a high fat content also have a high energy density. Therefore, a meal can have the same weight or volume, but at the same time the fat content and thereby the energy content can vary considerably(9). This could be an advantage for older adults with a decreased appetite, who prefer smaller portions but require a higher energy intake because of the risk of malnutrition.

According to nutritional guidelines for adults, the dietary intake of total fat should be in the range of 20–35 E% of the total energy intake. Food containing SFA, such as full-fat dairy foods, solid fats and red and processed meat, should be limited to <10 E%, and food with trans fats, such as biscuits/cookies and crisps/potato chips, should be avoided (<1 E%). Instead, the diet should contain more food containing MUFA and PUFA, such as vegetable oils (olive or rapeseed oils), soft margarines, nuts and oily fish(10). The aim of these recommendations is to decrease the risk of diet-related conditions such as CVD and overweight/obesity(11). However, frail and sick older adults seldom have problems with

overweight and obesity, but instead have a higher risk and pre-
valence of malnutrition(12).

There is limited scientific evidence about the optimal fat
intake among older adults in general and among older adults
with malnutrition problems in particular(12). General recom-
mendations for specific groups such as older adults have not yet
been established(10). Thus, the question remains whether pre-
vious fat intake among middle-aged and older adults affects
nutritional status in later life. This knowledge might facilitate the
taking of preventive action before malnutrition occurs.

The aim of the present study was to examine whether a high
dietary intake of fat among middle-aged and older adults is
associated with the risk of malnutrition 10 years later. The
hypothesis was that a previous higher energy intake from total
fat would be associated with a decreased risk of malnutrition
10 years later, irrespective of the composition of fat.

Methods

Study design and setting

The data originated from three different cohorts in central
Sweden: the Swedish Mammography Cohort (SMC), the Cohort
of Swedish Men (COSM) and the Västerås Nutritional Assess-
manship Study (VNAS). The SMC and COSM are two large
population-based prospective cohort studies conducted in
1987–1990 (SMC) and in 1997 (SMC and COSM), which were
designed to collect data on dietary intake and lifestyle factors as
risk factors for chronic diseases among middle-aged and older
adults(13,14). The VNAS was conducted from March 2008 to May
2009 with the aim of assessing the nutritional status of people
aged ≥ 65 years admitted to hospital(14). The study population in
the present prospective cohort study comprised participants
who were included in the SMC or COSM cohorts at the baseline
(1997) and in the VNAS cohort at the follow-up (2008–2009).

Study population

Swedish Mammography Cohort/Cohort of Swedish Men. The
SMC included all women born in the period 1914–1949 and
residing in central Sweden (Västmanland or Uppsala counties).
These women received a mailed self-administered ques-
tionnaire about diet, together with an invitation to participate in
a free-of-charge mammography screening programme(14). In
1997, an updated and extended questionnaire was sent to
participants who were still alive and who lived in the study area.
This questionnaire contained 350 items about dietary intake and
lifestyle factors (e.g. alcohol consumption, cigarette smoking,
sleeping habits, education and employment), as well as self-
reported medical history(14).

The COSM included all men born in the period 1918–1952 and
residing in central Sweden (Västmanland or Örebro counties).
Except for a few sex-specific questions, these men received the
same mailed questionnaire as the participants in the SMC(13). The
study populations have been described in detail previously(13,14).
The analyses in the present study are based only on questions
from the 1997 questionnaire in which the same wording was used
for both the SMC and the COSM. In this article, the SMC and
COSM cohorts are treated as a single cohort and are referred to as
the SMC/COSM cohort.

Västerås Nutritional Assessment Study. The VNAS included
patients aged ≥65 years admitted to the medical, surgical or
orthopaedic wards at a medium-sized county hospital in central
Sweden (Västmanland county). During the hospital stay, the
nutritional status of the participants was assessed by the Mini
Nutritional Assessment (MNA) screening instrument. The study
population has been described in detail previously(14).

Study population of the present study. To examine the
association between previous dietary fat intake and current
nutritional status, the personal identification numbers for the
participants in the SMC/COSM were linked with the personal
identification numbers from the VNAS to identify those who
were included in both studies. In total, 732 participants (n = 378
women, n = 354 men) were identified. After excluding individuals
with values outside ±5 from the mean of the logarithmised
intakes of total energy, total fat, carbohydrates, proteins or
alcohol, 725 participants were included in the present study.
A flowchart describing the recruitment of participants is
presented in Fig. 1.

The SMC, COSM and VNAS were approved by the regional
ethical review board in Stockholm, Sweden, the ethics com-
mittee at the Karolinska Institutet (Stockholm, Sweden) and the
Regional Uppsala Ethical Review Board, respectively. In the
SMC/COSM cohort, it was regarded as consent when the par-
ticipants returned the questionnaire. All participants in the
VNAS provided their written informed consent before entering the
study or, for participants unable to communicate, a relative
was asked whether he/she objected to the patient’s participa-
tion in the study.

Data collection

Dietary assessment in the Swedish Mammography Cohort/
Cohort of Swedish Men. A ninety-six-item FFQ was used to
assess the diet at the baseline. Participants were asked to report
how often, on average, they had consumed various foods and
beverages during the past year, with eight predefined frequency
categories ranging from never to ≥ 5 times per day. The nutrient
intake was calculated by multiplying the frequency of intake
from every food item with its nutrient content per portion,
based on the normal-size portions defined by the database of
the Swedish National Food Administration(15). The FFQ showed
moderately strong correlations among men (Spearman’s
r = 0.7, 0.8, 0.7 and 0.5 for total fat, SFA, MUFA and PUFA,
respectively)(16), when comparing the nutrient estimates based
on the FFQ with the total intake of nutrients from fourteen
24-h recall interviews.

Nutritional assessment in the Västerås Nutritional
Assessment Study cohort. The validated MNA screening
instrument(17,18) was used to evaluate the nutritional status at
the follow-up. This instrument is designed to assess the
nutritional status in people aged ≥65 years and comprises
Statistical analyses

The outcome of interest in the present study was the nutritional status at follow-up (≥265 years of age), as assessed by the MNA. The risk factors of main interest were the E% from total fat at the baseline on the nutritional status at follow-up. Of the main risk factors (total fat (E%), SFA (E%), MUFA (E%), PUFA (E%) and other fats (E%)), only those with univariate significance (P < 0.05) were included in the regression analyses. Because of a strong correlation between SFA (E%) and MUFA (E%) (Pearson's r = 0.770), total fat and SFA (Pearson's r = 0.926), total fat and...
MUFA (Pearson’s $r=0.936$), as well as between total fat and PUFA (Pearson’s $r=0.437$), separate regression models were constructed for total fat (E%), SFA (E%) and MUFA (E%). Both univariate and multivariate regression analyses were performed. The multivariate regression analyses were conducted in three steps, with nutritional status (reference group: well nourished) used as the response variable. First, all baseline variables with $P$ values $<0.20$ in the univariate analyses were included as explanatory variables and entered simultaneously into the base model. Second, statistically non-significant variables ($P>0.05$) were removed from the base model through a manual backward selection procedure, in which the variables with the highest $P$ values were removed one at a time and the model was re-estimated until the model included only statistically significant variables (reduced model). Third, all confounding variables included in the reduced model were tested for interaction effects with total fat (E%), SFA (E%) and MUFA (E%) by separately adding each interaction effect to the reduced model. Finally, all interaction effects with $P$ values $<0.05$ were added simultaneously to the reduced model. All significant interaction effects were retained in the models and formed the final models. In all steps, if a variable or an interaction between two variables was significant in any of the three models it was retained in the other models. In the final model, the total effects given by adding the main and interaction effects are presented. IBM SPSS Statistics 20 (IBM Corporation) was used for all statistical analyses. For all statistical tests, a two-sided $P$ value $<0.05$ was considered significant.

Results

Participant characteristics

Of the 725 participants, 51.6% (n 374) were women. At baseline, the mean age was 66.7 (sd 7.3) years (range 53–80 years) for women and 66.7 (sd 6.9) years (range 53–79 years) for men. The mean energy intake was 7020 (sd 768) kcal/d for men. The mean BMI was 25 (sd 3.3) kg/m$^2$ for women and 26.0 (sd 3.5) kg/m$^2$ for men. The mean follow-up period was 10.87 (sd 0.5) years (range 10–12 years). At follow-up, 290 (40.0%) participants were well-nourished, 383 (52.8%) were at risk of malnutrition and fifty-two (7.2%) were malnourished according to the MNA. The mean age at follow-up was 77.5 (sd 7.2) years (range 65–92 years) for women and 77.5 (sd 6.9) years (range 65–90 years) for men.

Table 1 presents the baseline characteristics of the participants for anthropometric measurements, lifestyle factors, total energy intake and the energy-yielding nutrients grouped according to the nutritional status at the follow-up. The malnourished participants had a previously higher intake of total fat (E%), SFA (E%) and MUFA (E%) compared with well-nourished participants, although these differences were NS (Table 1). In all participants, those who had a higher energy intake from total fat also had a higher proportion of SFA ($P<0.001$) and a lower proportion of PUFA ($P<0.001$) (data not shown). The main dietary sources of SFA (%) and MUFA (%) consumed by the 725 participants are displayed in Table 2.

BMI at the baseline differed significantly between the three nutritional status groups: 23.7 kg/m$^2$ in malnourished participants, 25.6 kg/m$^2$ in participants at risk of malnutrition and 26.2 kg/m$^2$ in well-nourished participants ($P<0.001$). The intake of E% fat differed between participants with a BMI $<25$ and BMI $\geq 25$ kg/m$^2$ (data not shown). In participants with a BMI $<25$ kg/m$^2$, mean energy intake (E%) of total fat was higher in malnourished participants (32.6 (sd 6.4) ($P=0.044$)) and in those at risk of malnutrition (32.0 (sd 5.2) ($P=0.018$)) compared with well-nourished participants (30.6 (sd 4.7)) In participants with a BMI $<25$ kg/m$^2$, mean energy intake (E%) of SFA was higher in malnourished participants (15.4 (sd 3.8) ($P<0.012$)) and in those at risk of malnutrition (14.8 (sd 3.4) ($P<0.009$)) compared with well-nourished participants (13.8 (sd 3.4) ($P<0.009$)). In participants with a BMI $\geq 25$ kg/m$^2$, E% from total fat or SFA did not differ significantly between nutritional status groups (data not shown).

Association between dietary fat intake and nutritional status

The results from the univariate and three separate multivariate multinomial logistic regression models are presented in Table 3. The results show the magnitude of the association between E% from total fat, SFA and MUFA at the baseline and nutritional status at follow-up.

In the univariate logistic regression model, the risk of being malnourished increased significantly for each additional percentage point of energy intake from total fat ($P=0.044$), SFA ($P=0.023$) and MUFA ($P=0.042$) compared with the well-nourished participants, but there was no significant association for those at risk of malnutrition ($P=0.588$–0.838). After adjusting for confounding variables in the multivariate logistic regression analyses, the OR for being in the malnourished group increased from the base model to the reduced models for total fat and MUFA, but not for SFA.

In the final models, there were significant interaction effects between total fat, SFA and BMI. For participants with a BMI $<25$ kg/m$^2$, the OR of being at risk of malnutrition or being malnourished increased for each additional percentage point of energy intake of the following types of fats: by 6.5 and 10.6%, respectively, for total fat; by 11.8 and 19.6%, respectively, for SFA; and by 17.3 and 27.2%, respectively, for MUFA (Table 3). However, for participants with a BMI $\geq 25$ kg/m$^2$, there were no significant associations between risk of malnutrition and the intakes of total fat, SFA or MUFA. These results are illustrated in Fig. 2, which gives the estimated probability (%) of being malnourished or at risk of malnutrition compared with being well nourished according to (a) E% total fat, (b) E% SFA and (c) E% MUFA separately for individuals with BMI $<25$ and $\geq 25$ kg/m$^2$. The results are given for a typical participant in the study – that is, an individual of the median age of 67 years who is a non-smoker (77% of participants) and retired, on a disability pension or unemployed (73% of participants).

Discussion

Contrary to what was expected, a high energy intake from dietary fat among middle-aged and older adults was associated with an
increased risk of exhibiting malnutrition 10 years later. However, this applied only to individuals with a BMI < 25 kg/m² at the baseline. The OR for being at risk of malnutrition or being malnourished increased for each additional percentage point of energy intake from total fat (by 6·5 and 10·6%, respectively), saturated fat (by 11·8% and 19·6%, respectively) and monounsaturated fat (by 17·3% and 27·2%, respectively).

**Strengths and limitations**

This is the first study to examine the association between previous dietary fat intake during middle and old age and nutritional status in later life. The prospective study design allowed us to control for important participant characteristics recorded at the baseline.

One limitation is that diet was self-reported and was measured only at the baseline, which will inevitably lead to some error in the measurement of dietary fat intake and attenuated risk estimates, as well as making it impossible to monitor whether there is a change in dietary fat intake in the years before the nutritional screening of the participants.

In the validation studies of the FFQ, the correlation coefficients for fat intake were moderately strong in men. Another limitation is that only follow-up data regarding nutritional status were available. However, participants who were malnourished at the follow-up had a lower mean BMI at the baseline (23·7 kg/m²) compared with those at risk of malnutrition (25·6 kg/m²) and well-nourished participants (26·2 kg/m²), suggesting that the nutritional status may have been similar 10 years earlier. Another limitation was that nutritional status was assessed only for individuals admitted to hospital, which limits the generalisability of the results to other middle-aged and older adults. However, most of the participants were living at home (95·9%) before their admission to hospital, as only 4·1% were living in a nursing home. This indicates that the study population might be healthier and have more similarities with the general public.

In addition, the study population in the present study included a selection of survivors because, obviously, only those who had
survived until the start of the VNAS could participate. Individuals with a high intake of dietary fat might have had a higher risk of dying,\(^{22}\) meaning that only survivors were selected in the study cohort. Consequently, there is a risk that a high energy intake from fat as a risk factor for future malnutrition might be underestimated in the present study. Finally, because of the observational study design, there is a possibility of residual confounding because other unmeasured or imprecisely measured risk factors for malnutrition, such as the presence of other diseases, may have affected the results. However, the present study population comprised healthy adults at the baseline, and for that reason the prevalence of self-reported diseases was low. Physical activity might be an important confounder related to both malnutrition and fat intake. Level of physical activity was analysed in relation to nutritional status (data not shown). However, there were no statistically significant differences in physical activity among the nutritional status groups, and the variables were therefore not included in further analysis.

### Meaning of the study: possible explanations of the results

Interpreting the association between a high fat content in the diet and malnutrition is complex because similar studies have not been reported. One likely explanation to the association is that malnourished individuals might have had a lower total energy intake (kJ (kcal)) at baseline. Total energy was, however, adjusted for in the regression analyses, but it was found to be non-significant and thus excluded from the reduced model. This indicates that total energy intake had no significant impact on the outcome, suggesting that the % of dietary fat may be the most important factor for predicting malnutrition.

A high energy intake from total fat could be a marker of poor nutrition, as energy density, nutrient composition and palatability of food are rarely separated in real life\(^{35}\). High energy diets usually contain foodstuffs with a high level of fat and sugar, such as snacks, fast food and desserts\(^{22,24}\). Therefore, individuals who consume more energy-dense food might lack other essential nutrients in the diet, which may lead to future malnutrition. The results from the present study partly support this theory because participants with a higher energy intake from total fat also had a higher proportion of SFA and a lower proportion of MUFA.

According to the dietary recommendations for adults\(^{30}\), the diet should include a high intake of food containing unsaturated fats such as vegetable oils (olive or rapeseed oils), soft margarines made from olive or rapeseed oils, nuts, chicken and avocados. However, in the present study, the main sources of MUFA originated from food items that also contained a high level of SFA (e.g.

The table displays the confounder BMI < 25 kg/m\(^2\) (reference BMI ≥ 25 kg/m\(^2\)) in all of the models (univariate, base, reduced and final), as it was used as an interaction term of total fat, SFA and MUFA in the final model. Energy percentage (%E) was used as a continuous variable; that is, the OR shows an increased or decreased risk of being at risk of malnutrition or being malnourished for each additional percentage point of energy from fat.

* The reference category is the well-nourished group (BMI < 25 kg/m\(^2\)).

† Reference category: BMI < 25 kg/m\(^2\).

‡ Controlled for total energy intake (kcal), protein (%E), sex, age, BMI, cigarette smoking, alcohol consumption, employment, high blood pressure and high cholesterol concentration.

§ Controlled for age, BMI, cigarette smoking and employment.

¶ Controlled for age, BMI, cigarette smoking, employment and the interaction term between total fat, SFA, MUFA and BMI. The total effects given by adding the main and interaction effects are presented.

† P = 0.010 for interaction between total fat and BMI < 25 kg/m\(^2\) in individuals at risk of malnutrition, P = 0.444 for interaction between total fat and BMI < 25 kg/m\(^2\) in malnourished individuals.

‡ P = 0.002 for interaction between SFA and BMI < 25 kg/m\(^2\) in individuals at risk of malnutrition, P = 0.192 for interaction between SFA and BMI < 25 kg/m\(^2\) in malnourished individuals.

¶ P = 0.066 for interaction between MUFA and BMI < 25 kg/m\(^2\) in individuals at risk of malnutrition, P = 0.958 for interaction between MUFA and BMI < 25 kg/m\(^2\) in malnourished individuals.
Fig. 2. Estimated probability (%) of being malnourished or at risk of malnutrition compared with being well nourished according to (a) energy percentage (E%) total fat, (b) E% saturated fat and (c) E% monounsaturated fat. The estimated probabilities were calculated from the final multivariate multinomial logistic regression models for individuals who in 1997 were 67 years old, non-smokers, retired, on a disability pension or unemployed, analysed separately for individuals with a BMI < 25 kg/m² and a BMI ≥ 25 kg/m².
full-fat cheese, butter/margarine on bread) (Table 2). Because the main sources of SFA and MUFA originated from the same food items (Table 2), we cannot exclude the possibility that these dietary components acted as confounding factors. Another explanation for why individuals with a high intake of MUFA were at an increased risk of malnutrition might involve trans fatty acids included in the MUFA\(^22\) because trans fatty acids exhibit the same properties as SFA.

The effect of a high energy intake from fat as a risk factor for malnutrition was no longer significant for participants with a BMI \(\geq 25\) kg/m\(^2\) – that is, when the interaction term of BMI was added to the final regression models. One possible explanation is that participants with a BMI < 25 kg/m\(^2\) had a higher E\% of total fat and SFA compared with those with a BMI \(\geq 25\) kg/m\(^2\). Alternatively, a high BMI might have such a strong protective effect against malnutrition that a high E\% intake from fat is not a risk factor for malnutrition in people with a BMI \(\geq 25\) kg/m\(^2\).

**Clinical implications**

To establish specific recommendations about energy intake from fat, both for older adults in general and for adults either at risk of or already experiencing malnutrition, the hypothesis that a previous high energy intake from dietary fat can prevent malnutrition in later life should be tested in an experimental study. The results of the present study suggest that a high energy intake from fat might have the opposite effect. These findings suggest that dietary recommendations for middle-aged and older adults should focus on reducing the intake of total fat in the diet by limiting food items containing SFA and MUFA.

**Conclusion**

Contrary to our expectations, a high energy intake from total fat, SFA and MUFA among middle-aged and older adults increased the risk of developing malnutrition 10 years later. However, this only applied to individuals with a BMI < 25 kg/m\(^2\) at the baseline. These findings suggest that preventive actions to counteract malnutrition in older adults should focus on limiting the intake of total fat in the diet by reducing consumption of food with a high content of saturated and monounsaturated fat, such as full-fat dairy foods, solid fats, processed meat and sugar-sweetened foods.
