Abstract. Within the 'earliest phases of star formation' (EPoS) Herschel project, we observed the NH$_3$ inversion lines of 6 very young high-mass star-forming regions at high spatial resolution (3-5\arcsec) with the JVLA. While the Herschel data provide details about the dust continuum, the ammonia data reveal the kinematics and temperatures. Here we present the exciting star-forming clump ISOSS23053 that shows multiple velocity components. We observe a prominent velocity step within the clump, which could be a sign of colliding or converging flows that triggers star formation. Furthermore, we used the JVLA in the C-array configuration to study this source in more detail and we present the first results from the new data. They support the idea of converging flows, as we observe two components in the NH$_3$(1,1) and (2,2) line, whereas the higher excited NH$_3$(3,3) line shows one component that links the two lower excited lines.

Keywords. Stars: formation - Stars: massive - ISM: clouds - ISM: kinematics and dynamics

1. Introduction

Even though the understanding of high-mass star formation has made tremendous progress over the past decade (e.g., Zinnecker & Yorke 2007; Tan \textit{et al.} 2014), the initial conditions are still poorly constrained. The most prominent candidates for young massive clumps are the infrared dark clouds (IRDCs). With the Herschel bolometers, we encompass the transition from continuum absorption to emission in these objects, but such observations lack any kinematic information. As the formation process of stars is thought to be highly dynamic (e.g., Bonnell \textit{et al.} 2004; Klessen \textit{et al.} 2005), such information is crucial for constraining star formation theories. Follow-up observations of molecular lines are mandatory for investigating the kinematics of star-forming regions. For this project, we observed the NH$_3$(1,1) and NH$_3$(2,2) inversion transitions of ammonia because they probe the temperature and kinematics of dense gas (e.g., Ragan \textit{et al.} 2012b). We selected 6 very young high-mass star-forming clumps from the Herschel EPoS sample (Ragan \textit{et al.} 2012a) to map with the JVLA in the D (most compact) configuration. Within the velocity maps, we find signatures which may be linked to converging flows. The results of this sample are given in Bihr \textit{et al.} (2015). Due to the low spectral
resolution of these early JVLA observations, we were not able to resolve the lines and we could not determine the line width accurately. Hence, we observed two sources of our sample again with the JVLA in C-array to achieve a higher spatial, but also spectral resolution. In this proceeding, we present this data for the clump ISOSS23053.

2. ISOSS23053

The clump ISOSS23053 has a mass of $M \sim 500-900 M_\odot$ (Ragan et al. 2012a) and shows several indicators of star formation, such as high density dust peaks, spectral signatures of infall and signs of outflows (Birkmann et al. 2007). The infrared observations reveal two emission peaks at $70 \mu m$ (see contours in Fig.1). In contrast to this, the ammonia observations reveal a more clumpy structure and they show a steep velocity step with two components, revealing a difference of $\sim 1.5 km s^{-1}$. As seen in the left panel of Fig. 1, the velocity step is situated close to the far-IR emission peaks. The exciting question is, if this velocity step traces a converging flow, which triggers the observed star formation activity. Our previous observations (Bihr et al. 2015) were not able to answer this question unambiguously, as the spectral and spatial resolution was not sufficient. However, new observations at higher spectral resolution allow us to study this object in great detail. Here, we want to highlight the preliminary analysis of the higher excited NH$_3$(3,3) line, which is shown in the right panel of Fig.1. We observe a clear detection of this higher excited line at the location of the velocity step, which indicates higher kinetic temperature. In contrast to the two velocity components seen in the NH$_3$(1,1) and NH$_3$(2,2) lines, we detect a single component in the NH$_3$(3,3) line, which spans over both velocity components of the lower excited lines. This is another indicator that we see an interaction between the two velocity components, which may trigger the observed star formation activities.
