(Received 27 November 2006 – Revised 20 April 2007 – Accepted 30 April 2007)

This work was aimed at decreasing the glycaemic index (GI) of white wheat bread. Breads made with wheat flour (WF) or wholemeal flour (WMF) and fermented with baker’s yeast had similar values of resistant starch (RS; 1.4–1.7 %, starch basis). Sourdough Lactobacillus plantarum P1 and Lactobacillus brevis P2 favoured the highest formation of RS (approximately 5 %) when fermented with WF and WMF. The mixture (1:1) of WF and WMF (WF/WMF) was selected. The effect of dietary fibres, chemical or sourdough acidification on the hydrolysis index (HI) of WF/WMF bread was determined. Among fibres, only the addition of oat fibre (5 %) decreased the HI to 90.84 %. Lactic acid determined the lowest HI, and the effect was related to the decrease of pH. For the same decrease of pH, breads fermented with L. plantarum P1 and L. brevis P2 (sourdough WF/WMF) showed values of HI lower than chemical acidification. The glucose response and GI of WF bread or sourdough WF/WMF bread enriched with oat fibre was determined by using fifteen healthy volunteers. Anhydrous glucose was used as reference. The area under the glucose response curve and the value of GI (72 %) of WF bread were significantly (*p<0.05) higher than sourdough WF/WMF bread enriched with oat fibre (GI = 53.7 %). The decrease of GI of the sourdough WF/WMF bread may be due to both fibre content and decreased pH. Compared to WMF bread, sourdough WF/WMF bread, enriched with oat fibre, had higher specific volume, better cell crumb structure and more appreciated acidulous smell, taste and aroma.

Glycaemic index: White wheat bread: Lactobacilli: Oat fibre

The glycaemic index (GI) is the measure of the power of food to raise the concentration of B-glucose in the blood after a meal. GI is defined as the ratio between the incremental area under the B-glucose response curve of the tested meal containing 50 g digestible carbohydrates and the incremental area under the B-glucose response curve of the standard food, i.e. 50 g pure glucose. Overall, carbohydrates that break down quickly during digestion have a high GI since their B-glucose response is fast and high. Carbohydrates that break down slowly have a low GI¹. Several large-scale, observational studies from Harvard University (Cambridge, MA, USA) indicate that long-term consumption of a diet with high glycaemic load (GI times dietary carbohydrate content) is a significant independent predictor of the risk of developing type 2 diabetes²,³ and CVD⁴. More recently, evidence has been accumulating that a low-GI diet might protect against development of obesity⁵, colon cancer and breast cancer⁶. The mechanisms of protection of the low-GI diet may derive from: (1) the slow release of carbohydrates in the upper gastrointestinal tract; (2) the lowering of the insulin demand⁷; and (3) the generally high concentration of indigestible carbohydrates such as dietary fibre and resistance starch (RS), which, in turn, increase the fermentative activity at the colon level. This latter fermentative activity increases the synthesis of propionic acid which is considered the moderator of hepatic glucose⁸ and lipid metabolism⁹. Therefore, the low-GI diet has emerged as an interesting tool in decreasing diseases related to the metabolic syndrome and cereal fibres have been shown to possess a preventative effect (for reviews see Jenkins et al.¹⁰ and Björck & Liljebæg¹¹). Based on experimental and epidemiological evidence, the development of low-GI cereal products seems to be particularly relevant from a metabolic perspective¹¹. Bread biotechnology as well some bread components may have an influence on glycaemia. Bread leavening by sourdough or the direct addition of acetic, propionic and lactic acids during bread making decreased the postprandial blood glucose and insulin responses (for review see Björck & Liljebæg¹¹). Cereal grains are mainly composed of starch and NSP such as β-glucan, polyfructan and arabinoxylan. Some of these polysaccharides are partially digestible, e.g. starch, while

Abbreviations: GI, glycaemic index; HI, hydrolysis index; RS, resistant starch; WF, wheat flour; WF/WMF, WF and WMF in the ratio of 1:1; WMF, wholemeal flour; δpH, decrease of the initial pH of the dough.

others are believed to serve as dietary fibres, e.g. arabinoxyllan\textsuperscript{12}. These dietary fibres exert beneficial effects on the reduction of the level of cholesterol and on decreasing the risk of colon cancer (for review see Jenkins et al.\textsuperscript{13}). Nevertheless, white bread, the most commonly consumed, is manufactured from wheat flours which have a very low concentration of these dietary fibres. Currently, the biotechnology of white bread is considering the manufacture of baked goods enriched with dietary fibres. When fibres or wholemeal are included in the formulas of baked goods, the protocol of manufacture needs the set up of several technological parameters in order to get high-quality and consumer-acceptable breads\textsuperscript{11,14}.

The present work was aimed at decreasing the GI of white wheat flour (WF) bread by using selected sourdough lactobacilli and dietary fibres. The GI of selected bread was determined \textit{in vivo} for fifteen healthy volunteers, and the structural and sensory properties of the resulting bread were characterized.

Materials and methods

Strains and culture conditions

\textit{Lactobacillus sanfranciscensis} DA110, \textit{L. plantarum} DC400 and P1, and \textit{L. brevis} P2, belonging to the Culture Collection of the Dipartimento di Protezione delle Piante e Microbiologia Applicata, Università degli Studi di Bari, Italy, were used in the present study. Strains were selected previously based on the acidification capacity. Strains were routinely propagated on MRS agar plates (Oxoid, Basingstoke, UK) with the addition of fresh yeast extract (5% v/v) and 28 mm-maltose at final pH 5.6.

Wheat flour breads fermented with sourdough lactobacilli: preliminary screening

The white WF (\textit{Triticum aestivum}, var. S. Pastore) used had the characteristics reported in Table 1. \textit{L. sanfranciscensis} DA110, \textit{L. plantarum} DC400, \textit{L. plantarum} P1 and \textit{L. brevis} P2 were used for dough fermentation to select the most appropriate starter based on the formation of resistant starch (RS). Cells of each strain (24 h old) cultivated in modified MRS were harvested by centrifugation (9000g, 10 min, 4\degreeCelsius), washed twice with 50 mm-sterile potassium phosphate buffer (pH 7.0) and resuspended in sterile distilled water to a final optical density at 620 nm of 2.5 (10\textsuperscript{9} colony-forming units/ml). WF (312 g), 133 g sterilized distilled water and 50 g of wheat flour (WF) bread by using selected sourdough lactobacilli and dietary fibres. The GI of selected bread was determined \textit{in vivo} for fifteen healthy volunteers, and the structural and sensory properties of the resulting bread were characterized.

WF (312 g), 133 g sterilized distilled water and 50 g of the cellular suspension, containing 10\textsuperscript{9} colony-forming units/ml of DA110, DC400, P1 or P2 strains (final cell number of approximately 5 \times 10\textsuperscript{8} colony-forming units/g dough), and 5 g baker’s yeast were used to produce 500 g dough (dough yield, dough weight \times 100/flour weight, 160) with a continuous high-speed mixer (60 g; dough mixing time, 5 min; Chopin & Co., Boulogne, France). A control dough without bacterial inoculum was prepared also. All the doughs were fermented at 30\degreeCelsius for 3 h and baked at 220\degreeCelsius for 50 min. All experiments were carried out using wholemeal flour (WMF) also (Table 1).

Bread making with dietary fibres, chemical acidification or sourdough

Three different dietary fibres (dextran, sugarbeet and oat fibres) were kindly supplied by Puratos n.v. (Groot-Bijgaarden, Belgium). The chemical composition of the dietary fibres is shown in Table 1. The following flours and fibres were used: (1) WF; (2) WMF; (3) WF and WMF in the ratio of 1:1 (WF/WMF); (4) WF/WMF and dextran; (5) WF/WMF and sugarbeet fibre; and (6) WF/WMF and oat fibre (Table 2).

To study the influence of chemical acidification, the following ingredients were used: (1) WF/WMF; (2) WF/WMF acidified with acetic acid to decrease the initial pH of the dough by 0.5 unit (\textDelta pH 0.5); (3) WF/WMF acidified with a mixture of lactic and acetic acids (ratio of 1:1) to \textDelta pH 0.5; and (4) WF/WMF acidified with lactic acid to \textDelta pH 0.5, 1.0 or 1.5 (Table 2).

\textit{L. plantarum} P1 and \textit{L. brevis} P2 were selected and used as sourdough to ferment dietary fibre-enriched breads. The initial cell density in the dough varied according to the \textDelta pH to be reached after 3 h of fermentation at 30\degreeCelsius (1 \times 10\textsuperscript{7}, 5 \times 10\textsuperscript{7} or 5 \times 10\textsuperscript{8} colony-forming units/g for \textDelta pH 0.5, 1.0 or 1.5, respectively). All WF, WMF and WF/WMF were fermented by sourdough to \textDelta pH 0.5, 1.0 or 1.5. Sourdough WF/WMF, containing dextran, sugarbeet fibre or oat fibre, was also fermented to \textDelta pH 0.5–1.5 (Table 2).

All the doughs were fermented at 30\degreeCelsius for 3 h and baked at 220\degreeCelsius for 50 min. For each condition, three independent experiments were carried out.

Determination of pH and physico-chemical analyses

The values of pH were determined by a Foodtrode electrode (Hamilton, Bonaduz, Switzerland). Moisture was determined according to the standard American Association of Cereal Chemists method\textsuperscript{15}. Nitrogen content was measured by the semimicro-Kjeldahl method. Protein was calculated by multiplying the nitrogen concentration \times 5.7. Carbohydrates were determined by HPLC\textsuperscript{14}. Soluble, insoluble and total dietary

fibres were determined according to the American Association of Cereal Chemists method.16

Total starch was analysed as described by Holm et al.17 Factor conversion from glucose to starch was 0.9. The RS and potentially available starch was determined using the in vitro method described by Åkerberg et al.18 Factor conversion from glucose to starch was 0.9.

In vitro starch hydrolysis

The analysis of starch hydrolysis simulates the in vivo digestion of starch.19 All bread portions contained 1 g starch and were given in randomized order to ten volunteers. Subjects rinsed their mouths with tap water and subsequently chewed the bread products for 15 s (approximately fifteen times). They were told not to eat within 1 h prior to the experiment. The products were then expectorated into a beaker containing 50 mg of pepsin in 6 ml of 0.05 M-Na,K-phosphate buffer (containing 0.4 g/l NaCl) adjusted to pH 1.5 with 2M-HCl. Finally, the sub-

Glycaemic index in vivo test

Fifteen healthy non-smoking volunteers, eight women and seven men, aged 23–55 years, with normal BMI (21.5 kg/m²) and without drug therapy participated in the present study. Anhydrous glucose and two breads were used for the in vivo test: WF (control) and WF/WMF enriched with oat fibre (Table 2). Available carbohydrates of each bread and anhydrous glucose (50 g) were consumed in a random order on separate mornings after 10–12 h overnight fast. The analysis was carried out in triplicate: each volunteer consumed the same sample during a period of 3 d. Samples were consumed over 6 min with tap water. After anhydrous glucose or bread ingestion, capillary finger-prick blood samples (three or four drops) were taken from volunteers fasting (0 min) and after 15, 30, 45, 60, 75, 90, 105 and 120 min. Blood samples were collected into tubes and frozen at −20°C before analysis by the glucose oxidase (EC 1.1.3.4) method.20

The areas under the glucose-response curves for each sample were calculated geometrically, excluding beneath the fasting level. GI was calculated by expressing the glycaemic response area for the WF bread and sourdough WF/WMF bread enriched with oat fibre as the percentage of the mean response area of the 50 g anhydrous glucose ingested by the same volunteers.
The resulting individual GI values were averaged to obtain the GI value for WF bread and sourdough WF/WMF bread.

**Bread characteristics**

The determinations of bread mass and specific volume were carried out according to the American Association of Cereal Chemists 10–10 official method (AACC, 2000, St Paul, MN, USA).

The bread crumb grain was evaluated by using image analysis technology. Images of the sliced breads were captured using an Image Scanner (Amersham Pharmacia Biotech, Uppsala, Sweden). Images were scanned full scale at 300 dots per inch and analysed in grey scale (0–255). Image analysis was performed using the UTHSCSA ImageTool program (version 2.0; University of Texas Health Science Centre, San Antonio, Texas, available by anonymous FTP from maxrad6.uthscsa.edu). A threshold method was used for differentiating gas cells and non-cells. The threshold was determined according to the method of Crowley et al.21. Analysis was carried out on two sub-images of 500x500 pixels selected from within the bread slice. Two slices were analysed per treatment. Gas cell to total area ratio was recovered.

The laboratory acceptance panel was used to give an indication of consumer acceptance of the products under study22. Breads, baked the day before sensory testing, were served at room temperature and under normal (daylight) illumination. A serving of each bread, identified by code numbers, on a single tray was served to each panelist. Ten volunteers from laboratory staff evaluated each product for quality attributes: colour, flavour/aroma, elasticity, sweetness and dryness. Acceptability of each quality attribute was rated with a score from 0 (lowest) to 100 (highest)23.

**Statistical analysis**

Experimental data were subjected to ANOVA and pair-comparison of treatment means was achieved using Tukey’s procedure at P<0.05 using the statistical software Statistica Windows version 6.0. For the GI *in vivo* test, the analyses were carried out in triplicate and the capillary finger-prick blood samples (three or four drops) were taken from volunteers fasting (0 min) and after 15, 30, 45, 60, 75, 90, 105 and 120 min after ingestion of the sample.

**Results**

*Wheat flour breads fermented with sourdough lactobacilli: preliminary screening*

Breads were preliminary fermented with baker’s yeast alone or with sourdough lactobacilli and baker’s yeast at 30°C for 3 h. The concentrations of RS and potentially available starch are shown in Table 3. Values of RS for breads made with white WF or WMF and fermented with baker’s yeast were similar; they ranged from approximately 1-4 to 1-7 %(starch basis). The concentration of RS in breads made with WF and WMF and fermented by sourdough lactobacilli and baker’s yeast was approximately double (3.36–5.04 %). The highest formation of RS was found (P<0.05 %) in breads fermented with strains of *L. plantarum* and *L. brevis*. As a consequence, *L. plantarum* P1 and *L. brevis* P2 were selected for further studies. No significant differences (P<0.05 %) for RS were found when WF or WMF were fermented with sourdough lactobacilli. The same was found when the mixture (1:1) of WF and WMF (WF/WMF) was used (data not shown). Further experiments were carried out by using WF/WMF flour.

**Rate of in vitro starch hydrolysis of breads made with dietary fibres, chemical acidification and sourdough**

The rate of *in vitro* starch hydrolysis is considered to be a presumptive measure of the GI in healthy subjects18. Starch hydrolysis at 30–180 min and values of the hydrolysis index (HI) are reported in Table 4 and Fig. 1, respectively. In agreement with the concentration of RS, the rate of starch hydrolysis did not vary between breads made with WF or WMF and fermented by baker’s yeasts alone. Except for oat fibre, no decreases of the starch hydrolysis were found when the

6.‡ Fermented with sourdough lactobacilli and baker’s yeast.
other fibres were used. The HI of the bread made with WF/WMF and enriched with oat fibre was 90.84 %.

The effect of organic acids and related decreases of pH (ΔpH) were determined (Table 4; Fig. 1). Lactic and acetic acids were used since they represent the major fermentation end-products during sourdough fermentation\(^2\). Overall, the rate of starch hydrolysis of breads containing acetic and lactic acids was significantly (\(P<0.05\)) lower than non-acidiﬁed breads. Differences were found depending on the type and concentration of organic acids. In particular, the bread acidified with acetic acid to \(\Delta pH 0.5\) showed values of starch hydrolysis always higher than the corresponding bread acidified with lactic acid (Table 4). As expected, the values of the starch hydrolysis found with the mixture of lactic and acetic acids were intermediate. Besides, the rate of starch hydrolysis and HI decreased proportionally with the increase of ΔpH as set by lactic acid. After 180 min, the percentage of hydrolysed starch was 41.16, 35.72 and 29.27 for WF/WMF breads with ΔpH 0.5, 1.0 and 1.5, respectively. In agreement, the HI ranged between 74.54 and 59.62 %.

Selected sourdough lactobacilli were further used for bread making with enriched dietary fibres. The growth of sourdough lactobacilli was not affected by the addition of fibres (data not shown). Compared to sourdough fermented breads, the addition of dextran or sugarbeet ﬁbre did not modify the degree of starch hydrolysis (Table 4). For instance, the bread made with sourdough WF/WMF and enriched with dextran had values of HI of 70.58 and 57.38 % when ΔpH 0.5 and 1.5 were reached, respectively (Fig. 1). On the contrary, the addition of oat ﬁbre to WF/WMF fermented with sourdough lactobacilli to ΔpH 1.5 gave the lowest value (23.47 %) of starch hydrolysis (Table 4). In agreement, the HI was 47.65 % (Fig. 1).

Glycaemic index in vivo test

Bread made with sourdough WF/WMF enriched with oat ﬁbre with ΔpH 1.5 was used for the in vivo determination of the blood glucose level and GI since it was characterized by the lowest value of HI. The bread made with WF and fermented with baker’s yeast alone was used as the control since it was made under the same conditions, except for the use of WMF, sourdough lactic acid bacteria and oat ﬁbre. Anhydrous glucose was used as reference. All volunteers consumed anhydrous glucose and breads according to the experimental protocol. The mean incremental blood glucose response curves during 120 min after sample ingestion are shown in Fig. 2.

WF, white wheat flour bread; WF/WMF, WF and WMF in the ratio of 1:1; WMF, wholemeal flour bread; \(\Delta pH\), decrease of the initial pH of the dough.  
*a–e* Mean values within a column with unlike superscript letters were significantly different (\(P<0.05\)).  
*For details of ingredients and bread making, see Table 2 and Materials and Methods.*  
†Fermented with sourdough lactobacilli and baker’s yeast.
The GI of WF was approximately 72% of the reference (anhydrous glucose, GI = 100). During 120 min after bread ingestion, the blood glucose increment of sourdough WF/WMF bread was significantly (P<0.05) lower than that of WF bread. In agreement, the GI of sourdough WF/WMF bread enriched with oat fibre was approximately 53.7%.

**Bread characteristics**

Breads made with WF or WMF and fermented with baker’s yeast alone, and sourdough WF/WMF bread were analysed for volume, bread mass, specific volume, crumb grain and sensory characteristics. WF bread had a higher volume (approximately 1340 ml) than WMF bread (670 ml; Table 5). The volume of sourdough WF/WMF bread enriched with oat fibre was intermediate (997 ml). On the contrary, no significant (P<0.05%) differences were found for bread masses. Consequently, sourdough WF/WMF showed an increased specific volume (73.91%) compared to WMF bread (49.16%).

The bread crumb grain was determined by image analysis technology. Digital images were pre-processed to detect crumb cell-total area by a binary conversion (black/white pixels; Fig. 3). The cell-total area of WF bread (corresponding...
to the black pixel total area) was 46%. Crumb cell detection for WMF bread slices showed smaller and less numerous gas cells, as shown by the visual inspection of the binarized images of the breads. Indeed, a considerable variation of the cell-total area with respect to WF bread (17% v. 46%) was found. Substantial differences were found in the crumb features of sourdough WF/WMF bread enriched with oat fibre. The addition of WF and sourdough fermentation resulted in a larger gas cell-total area (38%) with respect to WMF bread (17%).

Overall, sourdough WF/WMF bread enriched with oat fibre showed a higher acceptability score than WMF bread (17%).

**Discussion**

Sourdough fermentation with selected lactobacilli improved the nutritional features of starch in white WF breads. All breads fermented with lactobacilli contained higher concentrations of RS than breads started with baker’s yeasts alone. Based on its definition, RS includes starches and their partial hydrolysis products that are not digested or absorbed in the small intestinal lumen of healthy persons. The main physiological influence of RS is concerning the: (1) inhibition of the postprandial increase of blood glucose and insulin; (2) decrease of the blood lipid concentration; and (3) decrease of the concentrations of ammonia, phenol and secondary bile acid in the colon. In agreement with previous studies, the concentration of RS (<20% starch) in white WF and WMF breads started with baker’s yeast alone was too low to significantly interfere with the glycaemic response. An increase of the RS was found in organic acid added or sourdough fermented pumpernickel breads. Indeed, selected sourdough *L. plantarum* and *L. brevis* strains caused the highest increase of RS in breads made with WF and WMF. Overall, the use of WMF did not influence the concentration of RS.

Consumption of foods naturally rich and/or enriched in cereal fibres is recommended to prevent several diseases. Nevertheless, a large gap between dietary recommendations and daily intake of fibres is currently present in the diet of a large part of the population. To enrich cereal baked goods with fibres by keeping optimal sensory properties is probably the most desirable goal. The present study considered the use of WF in a mixture with WMF and the addition of oat fibre also on the decrease of the postprandial glycaemic response. As also discussed later, the results of the present study suggest an effect of oat fibre also on the decrease of the postprandial glycaemic response.

Chemical acidification decreased the rate of starch hydrolysis and HI in breads. Acetic, propionic and lactic acids have the capacity to lower the postprandial blood glucose and insulin responses in man when included in the bread formula. Breads made with the mixture of WF/WMF showed the...
highest decrease of HI when lactic acid was used. The decrease of HI seemed to be concentration-dependent and the lowest values of HI were found for ΔpH 1.5. Overall, the lowering of glycemia and insulinaemia by lactic acid are not attributed to a decreased gastric emptying rate but to interactions between starch and gluten that limited the starch bioavailability. For the same values of ΔpH, the biological acidification of WF/WMF by sourdough *L. plantarum* P1 and *L. brevis* P2 showed a higher decrease of the rate of starch hydrolysis and HI with respect to chemical acidification. This agreed with a previous study on wholemeal barley flour breads produced by sourdough, lactic acid or sodium propionate (www.gilisting.com/2004/05/glycemic-index-of-breads.html).

Fig. 3. Representative images of breads made with white wheat flour (WF) (A, B) or wholemeal flour (WMF) (panel C, D) and fermented with baker’s yeast alone, and 1:1 WF/WMF enriched with oat fibre and fermented with sourdough lactobacilli to ΔpH 1.5 (E, F). (A, C, E), Digital images of bread showing the original grey level images; (B, D, F), computed binary results from grey level thresholding at the two-cluster. ΔpH 1.5, decrease of the initial pH of the dough by 1.5 units.
When WF/WMF was enriched with dietary fibres and fermented by sourdough lactobacilli only oat fibre caused a marked decrease in the rate of starch hydrolysis and showed the lowest HI. The in vivo challenge on fifteen healthy volunteers showed that this bread caused a lower blood glucose increment compared to bread made with WF and fermented with baker’s yeast alone. This bread was included in the analysis since it is consumed in large amounts in southern Europe. The value of GI calculated from glycaemic responses for sourdough WF/WMF bread enriched with oat fibre was significantly (P<0.05) lower than that of WF bread (approximately 53.7 and 72 %, respectively).

The sourdough WF/WMF bread enriched with oat fibre was also characterized for volume, mass, specific volume, crumb grain and sensory properties. Almost all these characteristics indicated a superior quality of sourdough WF/WMF bread enriched with oat fibre compared to bread made with WMF and fermented with baker’s yeast alone. In particular, sourdough WM/WMF showed an increased specific volume and a better cell crumb structure. In agreement with previous results, the cell-total area of the bread made with WF was 46 %. Total cell-area of sourdough WF/WMF bread enriched with oat fibre was only 8 % smaller than that of WF bread. Besides, sourdough WF/WMF bread enriched with oat fibre showed a more pronounced acidulous smell and taste, and an intense and more appreciated aroma with respect to WF or WMF breads. These sensory attributes are probably related to the complementary fermentative activities of L. plantarum P1 (facultative heterofermentative lactic acid bacterium) and L. brevis P2 (obligate heterofermentative lactic acid bacterium). In most European countries, bread constitutes the major source of dietary carbohydrates. Bread with decreased GI content frequently associated with low-GI foods may also add to the importance of dietary fibre and other food properties.
