Vitamin K distribution in rat tissues: dietary phylloquinone is a source of tissue menaquinone-4

BY H. H. W. THIJSSEN AND M. J. DRITTIJ-REIJNDERS

Department of Pharmacology, University of Limburg, PO Box 616, 6200 MD, Maastricht, The Netherlands

(Received 14 May 1993 - Revised 16 December 1993 - Accepted 14 January 1994)

The present study was undertaken to determine whether there is selective tissue distribution of vitamin K in the rat and whether this distribution mirrors the distribution of tissue vitamin K metabolism. The effects of feeding a vitamin K-free diet followed by resupplementation with phylloquinone (K₃) were studied. K₃ was recovered in all tissues. In K₃-supplemented rats, most tissues accumulated K₃ relative to plasma K₃, with the highest levels in liver, heart, bone, and cartilaginous tissue (sternum). Low K₃ levels were found in the brain. In the K₃-free rats, relatively high K₃ levels were still found in heart, pancreas, bone and sternum. Surprisingly, menaquinone-4 (MK-4) was detected in all tissues, with low levels in plasma and liver, and much higher levels in pancreas, salivary gland and sternum. MK-4 levels exceeded K₃ levels in brain, pancreas, salivary gland and sternum. Supplementation with K₃ orally and by intravenous infusion, caused MK-4 levels to rise. Some accumulation of K₃ and MK-4 in the mitochondrial fraction was found for kidney, pancreas and salivary gland. In the liver the higher menaquinones (MK-6–9) accumulated in the mitochondria. The results indicate that: (1) there is selective tissue distribution of K₃ and MK-4, (2) dietary K₃ is a source of MK-4. The results also suggest there may be an as yet unrecognized physiological function for vitamin K (MK-4).

Vitamin K: Menaquinone: Phylloquinone: Rat

It is accepted currently that vitamin K undergoes a cyclic interconversion, the vitamin K cycle, comprising the reduction of the vitamin K quinone form into the hydroquinone, the oxidation to the 2,3-epoxide (vitamin K epoxide), and the reduction to the quinone (vitamin K). The epoxidation of the hydroquinone is coupled to a carboxylase which converts glutamyl residues in substrate proteins to essential γ-carboxyglutamates (Gla). In the liver the products of this post-translational vitamin K-dependent carboxylation are the coagulation factors II, VII, IX, and X, and the anticoagulation proteins, protein C and protein S. The reductase(s) of the vitamin K cycle are the target of coumarin antagonists. The vitamin K cycle is embedded in the rough endoplasmic reticulum with the carboxylase facing the luminal site (for reviews, see Suttie, 1987; Vermeer 1990). Enzymes of the vitamin K cycle are also found in non-hepatic tissues but vitamin K-dependent products have been found only in bone (bone Gla protein and matrix Gla protein; Hauschka et al. 1989) and endothelial cells (protein S; Fair et al. 1986). At the present time no physiological function or dysfunction associated with vitamin K other than haemostasis has been demonstrated, except skeletal malformations due to fetal exposure to warfarin (Hall et al. 1980). Thus, the physiological function of the non-hepatic vitamin K cycle is an unresolved phenomenon.

We reasoned that if there is a function for the extrahepatic vitamin K cycle the selective tissue distribution of vitamin K should mirror the biochemical activity of the cycle. Thus,
'high' vitamin K levels are anticipated in tissues such as liver, pancreas, bone etc. which have high vitamin K-related activities, with low levels in tissues such as heart and brain which are devoid of any vitamin K cycle-related activity.

In the present study we report on the tissue distribution of phylloquinone (K,) in the rat and the effect of dietary K, restriction. The results show that the selective distribution of K, in tissues is not strictly related to biochemical activity. Surprisingly, the completely prenylated variant of K,, i.e. menaquinone-4 (MK-4; Fig. 1), was found in all extrahepatic tissues in high amounts. Furthermore, the results of the dietary experiment suggested that the presence of MK-4 is related to the supply of K,.

MATERIALS AND METHODS

Male Wistar rats (200–220 g) were divided in two groups of five animals and fed for 9 d on either a K,-deficient diet or a diet which was supplemented with K,. The rats were housed individually in metabolism cages with raised wired bottoms to prevent coprophagy. Rats were maintained in a 12 h light-dark cycle at a temperature of 21 ± 1° and 50% humidity. The K,-free diet was supplied by Hope Farms (Woerden, The Netherlands) and consisted of (g/kg): vitamin K-free casein 20, methionine 2, choline 4, maize starch 100, sunflower oil 50, cellulose 50, glucose 480, and standard amounts of minerals, trace elements and vitamins (except menadione). The diet was subjected to γ-irradiation (2 MRad) to destroy any natural K,. The K, content was less than 5 ng/g (our own analyses). The diet was powdered and mixed 1:1 (w/w) with commercially available ordinary baby rice flour. It has been shown previously by Mathers et al. (1990) that a rice diet suppresses menaquinone-producing intestinal bacteria in the rat. The K, -supplemented diet was prepared by thoroughly mixing a powdered K, formulation (Konakion formulation (50 g K, /kg); Hoffman La Roche, The Netherlands) with the diet. It was intended to prepare a diet containing 2 µg K, /g diet, i.e. about the level of normal lab chow. However, the analyses at the end of the experiment revealed a K, content of 4.2 µg/g. The diet was presented ad lib. The rats exhibited a normal feeding pattern, with a weight gain of 35–45 g/week.

In a second experiment, which arose from the results of the first experiment, eight rats were fed on the vitamin K-deficient diet for 6 d. From day 7 on, three rats were given K,
(Konakion in mixed micelles) by continuous intravenous infusion (2 μg/h) via an implanted cannula in the *vena jugularis*. The vitamin was administered using a subcutaneously implanted osmotic minipump (Alza Corporation, Palo Alto, CA, USA). Three rats were given the diet supplemented with K1 (2 μg/g). The remaining two rats served as controls. The experiment ended at day 11. The protocols were approved by the University Ethical Committee for experimental animals.

At the end of the experiments the rats were killed; under light diethyl ether anaesthesia blood was withdrawn from the abdominal aorta and the blood was mixed 9:1 (v/v) with 0.1 M-trisodium citrate. Immediately after death the rats were perfused with cold (4°C) saline (9 g NaCl/l) via the heart and the following organs (tissues) were excised: pancreas, liver, kidney, heart, lung, submaxillary gland, brain, muscle (thigh), femur bone, and sternum. The organs (except bone) were immersed immediately in ice-cold saline. Tissue homogenates in phosphate-buffered saline (1:3 w/v; wet-weight basis) with (for pancreas and salivary gland) or without a cocktail of protease inhibitors (soya-bean trypsin (EC 3.4.21.4) inhibitor 50 μg/ml, aprotonin 1 μg/ml, benzamidine 0.1 mg/ml; PMFS 0.1 mg/ml; EDTA 1 mM), were prepared with a blender (Ultra Turrax; Janke & Kunkel, Staufen, Germany) followed by further treatment in a Potter homogenizes (three strokes at 1100 rpm; Braun, Melsungen, Germany). The homogenates were stored at −70°C until assayed. The femur bone and the sternum was scraped free of adhering tissue as much as possible. The femur was slivered carefully and the marrow was dispersed in 0.5 ml cold phosphate-buffered saline by vortex mixing on a whirl mixer and the bone slivers were separated.

Tissue mitochondrial, microsomal and cytosolic fractions (100000 g supernatant fraction) were prepared by standard procedures from pooled organs of two rats fed on standard lab chow. The mitochondria as well as the microsomes were repeatedly washed by resuspension and resedimentation respectively.

Prothrombin time was assayed using the thrombotest (R) reagent (Nycomed AS, Oslo, Norway) according to the manufacturer’s instructions.

**Vitamin K analyses**

As vitamin K is light sensitive, all procedures were performed under orange–yellow light. Homogenates (0.5 ml and 0.25 ml for the vitamin K-free and -supplemented samples respectively) in a glass tube with a Teflon-lined screw cap were made up to 1 ml with water and mixed thoroughly with 2 ml ethanol containing 400 pg 2′,3′-dihydrophylloquinone as internal standard for 30 min on a horizontal shaker. The mixture was extracted with 3–5 ml hexane. After evaporation to dryness under N2 at 30°C, the residue was dissolved in 5 ml hexane and loaded onto a silica column (500 mg silica 60, 40–63 μm, Merck, Darmstadt, Germany). The column was eluted with 5 ml hexane containing 5 ml ethyl acetate/l (fraction discarded) whereafter the vitamin K-containing fraction was eluted with 5 ml ethyl acetate in hexane (20 ml/l). Loading, washing and elution were performed using a solid-phase extraction manifold (Supelco, Leusden, The Netherlands). The bone and sternum were extracted as follows: the chopped sternum and the bone slivers in a glass tube were placed under vacuum (solid-phase extraction manifold) whereafter 0.5 ml ethanol containing the internal standard was injected. Following an overnight period, 0.5 ml water was added and the samples were homogenized using the Ultra Turrax.

The vitamin K fraction was analysed by fluorescence detection following HPLC separation and post-column reduction (Thijssen & Drittij-Reijnders, 1993). A Jasco 821-FP fluorescence detector (excitation 244, emission 430 nm) was used. Calibration curves for vitamin K measurements were prepared using solutions of K1 and MK-4 in albumin in
Sample (plasma, homogenate), 0.25–0.5 ml, up to 1 ml with water

- 2 ml ethanol containing internal standard
- Mix for 30 min
- 3–5 ml n-hexane
- Extract and collect the upper layer
- Evaporate
- 5 ml n-hexane
- Apply to a silica gel column
  - wash with 5 ml ethylacetate in n-hexane (5 ml/l)
  - elute with 5 ml ethylacetate in n-hexane (20 ml/l)
- Evaporate
- 50 μl propan-2-ol
- 50 μl methanol

HPLC analysis: column Chromspher C18 100 × 3 mm, eluent methanol–propan-2-ol–water (450:50:7, by vol.) containing 40 mg tetramethylammoniumoctahydrotriborate/100 ml. Post-column: electrochemical cell with -0.8 V setting. Fluorescence detection excitation 244 nm, emission 430 nm.

Fig. 2. Flow diagram of vitamin K analysis.

Phosphate-buffered saline (40 g/l) and in plasma of K₁-deficient rats. The calibration curves of K₁ and menaquinones-4–9 (MK-4–9) were linear up to at least 4 ng/ml. Fig. 2 shows a flow diagram of the vitamin K analysis.

K₁ and MK-4 were obtained from Sigma Chemicals (St Louis, MO, USA). MK-6–9 and 2',3'-dihydrophylloquinone were provided by Hoffman La Roche (Basle, Switzerland).

RESULTS

Rats fed on the K₁-deficient diet showed a prolonged prothrombin time, although the response of the individual rats differed greatly (Table 1).

In addition to K₁, MK-4 was present in extracts from all tissues (Fig. 3). Traces of MK-6 were found also in some liver extracts, but higher menaquinones were not found (Fig. 3). As a control for the homogeneity of the vitamin K peaks, samples of all tissues were initially rerun without post-column reduction. This showed that liver extracts contained endogenous fluorescing compounds, one of which interfered with MK-6 (Fig. 3). The other tissue extracts appeared to be free of endogenous fluorescing peaks.

Fig. 4 shows tissue K₁ and MK-4 distribution in the rat. In K₁-supplemented rats, all tissues examined showed levels in the nanogram range and, except for brain tissue, the tissue levels were higher than those for plasma. High K₁ levels were found in liver and heart (101 (SD 28) and 77 (SD 21) ng/g wet weight tissue respectively). Relatively high K₁ levels were also found in bone tissue, particularly in bone marrow (13 (SD 2) ng/g bone).

MK-4 distribution revealed remarkable results. Selective tissue distribution is apparent, with very high levels (> 100 ng/g) in pancreas and salivary gland, low levels in plasma and...

Fig. 3. (a, b), Chromatograms of extracts of tissues of rats fed on a phyloquinone (K₄)-supplemented diet. ↓, Menaquinone (MK)-6, MK-7, MK-8 and MK-9 respectively. Peaks 1, 2 and 3 represent MK-4, K₄ and internal standard respectively. (c), Chromatogram of a liver extract without post-column reduction. ↓, MK-4, K₄ and internal standard respectively. For details of diets and procedures, see pp. 416-418.
The tissue K\textsubscript{1} levels in rats maintained on the K\textsubscript{1}-deficient diet for 9 d were low (< 1 ng/g), except for heart and bone which contained about 2 ng/g. The K\textsubscript{1}-deficient rats had lower MK-4 levels compared with the K\textsubscript{1}-supplemented rats. In most tissues the MK-4 levels were less than 10\% of those found in the K\textsubscript{1}-supplemented rats except for the pancreas, salivary gland, brain and sternum where the MK-4 levels were about half those of the K\textsubscript{1}-supplemented rats (Fig. 4).

The comparatively high MK-4 levels found in the K\textsubscript{1}-supplemented rats raised the question of whether MK-4 originates from the K\textsubscript{1} supplement or whether it reflects the conservation of MK-4 stores present at the start of the feeding. A second experiment was designed to study the effect of K\textsubscript{1} supplementation of vitamin K-deficient rats. The results are shown in Fig. 5; distribution patterns were similar to those found in the first experiment (Fig. 4). Tissue MK-4 levels increased in response to K\textsubscript{1} administration either orally or by intravenous infusion. The relative rise in MK-4 differed between tissues; liver levels increased 10–30-fold, although the absolute contents remained low (< 10 ng/g). Pancreas
and salivary gland showed a 2–4-fold increase; their levels were high: (97, 229 and 360 ng/g for the pancreas and 68, 225 and 280 ng/g for salivary gland in the K₁-deficient and orally and intravenously K₁-supplemented rats respectively). High K₁ levels were found in liver and heart of the K₁-supplemented rats.

The tissue distribution as well as the cellular distribution of K₁ and MK-4 was estimated in rats (n 2) on normal lab chow (K₁ content about 2 μg/g). The data are presented in Table 2. As for rats on the K₁-supplemented diets (Figs. 4 and 5), there was selective tissue distribution of K₁ and MK-4; elevated K₁ levels occurred in liver, heart, and pancreas, and low levels (< 1 ng/g) in brain tissue. Very high levels (> 100 ng/g) of MK-4 were found in pancreas and salivary gland and high levels (> 10 ng/g) in kidney, brain, and heart. In liver also MK-6–9 were recovered (menaquinones higher than MK-9 were not investigated).

K₁, phylloquinone; MK-4-9, menaquinones-4-9; KO, 2,3-epoxide of phylloquinone.
* For details of procedures, see pp. 416-418.

There appeared to be some mitochondrial accumulation of K₁ and MK-4 in kidney, pancreas, and salivary gland. In the liver there was selective distribution in the mitochondria for the higher menaquinones (MK-6–9).

DISCUSSION

The present study was undertaken to determine whether tissue K₁ distribution is related to tissue vitamin K metabolism, i.e. do tissues known to be rich in, for example, carboxylase activity also accumulate K₁? The results did not follow the pattern expected: K₁ was recovered not only in carboxylase-rich tissues (e.g. liver, kidney, lung, bone etc.) but also in tissues low in carboxylase (heart, brain and muscle). In particular the large accumulation of K₁ in heart tissue from K₁-supplemented rats was interesting. Hirauchi et al. (1989) reported on the distribution of vitamin K-active compounds in a limited number of tissues of the rat; they found that heart tissue contained K₁ in amounts comparable with those of liver.

Another unexpected finding was the recovery of MK-4 in all tissues examined. However, the identification of MK-4 and other vitamin K-active compounds in the tissue extracts was based on chromatographic data and on the reduction-dependent fluorimetric response (Fig. 3). The distribution pattern of MK-4 appears to be tissue-selective, showing that for most tissues the levels of MK-4 were higher than those of K₁, with very high levels in the pancreas and salivary gland; cartilaginous tissue (sternum) also appeared to be rich in MK-4. In fact, only liver and plasma appeared to contain low levels of MK-4. The findings also showed, contrary to expectation, that in the rat there was a relatively high body store of the vitamin (as MK-4), the majority being extrahepatic. Furthermore, the results suggested...
a direct relationship between tissue $K_1$ and MK-4; reduced MK-4 stores are replenished by feeding $K_1$.

While the present study was in progress, two independent groups reported high MK-4 levels in chick livers and found a relationship between MK-4 levels and dietary $K_1$ supply (Guillaumont et al. 1992; Will et al. 1992).

The intriguing question is: what is the source of MK-4? In the early days of vitamin K research, in vivo conversion of $K_1$ to MK-4 was reported by Billeter & Martius (1960). The conversion of $K_1$ to MK-4 is believed to proceed via menadione as an intermediate followed by the introduction of the geranylgeranyl side chain. The first step, the dealkylation of $K_1$, has been suggested to be mediated by bacterial (intestinal flora) metabolism (Billeter et al. 1964). The hypothesis that MK-4 is the true physiologically active form and that it is derived from dietary $K_1$ through bacterial metabolism can still be found in textbooks (Mutschler, 1991).

The conversion of MK-4 from menadione is well established (Taggart & Matschiner, 1969), in particular chick liver shows high (in vitro) activities in this respect (Dialameh et al. 1971). The standard commercial rat food used in our laboratory contained menadione (6 $\mu$g/g, value given by the manufacturer: Hope Farms, The Netherlands) as the added vitamin K-active compound. The $K_1$ content from natural sources, which varied from batch to batch, was found to be 1–2 $\mu$g/g (our own analyses). Thus, the tissue MK-4 in rats fed standard commercial food (Table 2) may be derived from dietary menadione, as may be MK-4 in the $K_1$-supplemented rats described in Fig. 4. Results shown in Fig. 5, however, rule out menadione; neither the vitamin K-deficient diet nor the $K_1$ formulations (Konakion dry formulation (50 g/kg) and Konakion mixed micelles formulation) that were used for supplementation of the diet and for intravenous infusion contained menadione. Two possible sources of MK-4 under the experimental conditions used could be: (1) MK-4 derived from $K_1$, (2) MK-4 of bacterial (intestinal flora) origin. The latter option assumes high bacterial production of MK-4 considering its poor colonic absorption (Ichihashi et al. 1992). However, MK-4 has been reported to be a minor bacterial product (Ramatot et al. 1984; Kindberg et al. 1987). Moreover, as was shown by Mathers et al. (1990), the addition of rice to the diet successfully suppressed bacterial menaquinone synthesis since there was an absence of higher menaquinones in liver (Fig. 3 cf. Table 2). Consequently, the most likely explanation is that MK-4 was derived from dietary $K_1$. The present findings do not distinguish between a possible bacterial pathway (Billeter et al. 1964) and tissue metabolism of $K_1$ to MK-4. The fact that the intravenous $K_1$ administration also was associated with raised tissue MK-4 levels (Fig. 5), as has been found to occur in chicken liver (Will et al. 1992), may point to tissue metabolism. However, entero-hepatic circulation of $K_1$ can not be ruled out. Assuming that MK-4 is derived from $K_1$, either by total $K_1$ conversion or by alkylation of bacterially-derived menadione, the question arises as to whether the tissue MK-4 is formed locally or whether it is delivered from a metabolic source, e.g. the liver. The low circulating MK-4 levels, even with intravenous administration of $K_1$, where high tissue MK-4 levels are encountered (Fig. 5), suggest specific tissue formation of MK-4.

Clearly, rather than bridging gaps in our understanding of potential extrahepatic functions of vitamin K, this study has generated new gaps in our knowledge. It is hard to believe that the high levels of the vitamin in tissues such as heart, pancreas, salivary gland etc. are related to a possible vitamin K-dependent post-translational carboxylase reaction. Its presence in the brain may be related to the reported vitamin K-dependent brain sulphotransferase activity (Sundaram & Lev, 1990). Consequently, additional physiological (biochemical) functions have to be attributed to the vitamin, in particular to MK-4. Based on the chemical similarity with ubiquinone, a function in the electron transport of the
mitochondrial respiration chain could be considered. Mitochondrial accumulation of vitamin K-active compounds was apparent in some tissues; however no mitochondrial accumulation was found in the heart (Table 2). Studies of $K_1$ biochemical vitamin K metabolism, i.e. vitamin K-epoxidation, in the extrahepatic tissues are in progress.

Considering the high density of the warfarin receptor (Thijssen & Baars, 1991) it was anticipated that $K_1$ would be present in pancreas and salivary gland tissue. Experiments have been planned to determine whether any relationship exists between the warfarin receptor and the high accumulation of MK-4. In this respect it is of interest to note that Taggart & Matschiner (1969) found that dicoumarol inhibits the in vitro alkylation of menadione to form MK-4.

The role of the bacterially-derived higher menaquinones in liver vitamin K metabolism is as yet unanswered. The livers of rats on the $K_1$-free diet did not contain detectable amounts of these vitamin K-active compounds demonstrating the effectiveness of rice supplementation (see p. 416). However, there was no clear-cut relationship between the prolongation of the prothrombin time and the individual liver $K_1$ levels (data not shown).

In summary, the present study shows a selective distribution of MK-4 and $K_1$ in the rat. The body store of MK-4 can be derived from the dietary $K_1$ supply. The findings suggest there is an as yet unrecognized physiological function of vitamin K. Information on tissues of other species have to be gathered to determine how widespread the observations are.
