The discovery of SO galaxies with polar rings makes it possible to directly measure the gravitational potential of a galaxy in three dimensions. Schweizer, Whitmore and Rubin (1983) find a spherical potential in the case of A0136-0801. We have observed three more polar ring galaxies using the 4 meter telescope at CTIO. The following table summarizes the results for these three systems as well as A0136-0801, and figure 1 shows an example of the data.

Galaxy	$V_{ring}/V_{disk}$	$\sigma_0$	$V_{disk}/\sigma_0$
A0136-0801	$0.94 \pm 0.17$	$67 \pm 7$	$2.3 \pm 0.3$
NGC 4650A	$0.90 \pm 0.11$	$77 \pm 8$	$1.6 \pm 0.2$
ESO415-G26	$1.07 \pm 0.13$	$127 \pm 6$	$1.4 \pm 0.2$
AM2020-5050	$0.32 \pm 0.07$	$159 \pm 12$	$0.4 \pm 0.1$

For the top three galaxies, a comparison of the rotational velocity of the SO disk to the perpendicular polar ring at the same radius ( $V_{ring}/V_{disk}$ ) provides a measurement of the shape of the gravitational potential. The average value of  $V_{ring}/V_{disk}$  for these galaxies is  $0.97 \pm 0.08$ , corresponding to a nearly spherical shape for the halo.

The low value of  $V_{disk}/\sigma_0$  (where  $\sigma_0$  is the central stellar velocity dispersion) for AM2020-5050 shows that the inner component of this system is probably an elliptical galaxy rather than an SO disk.

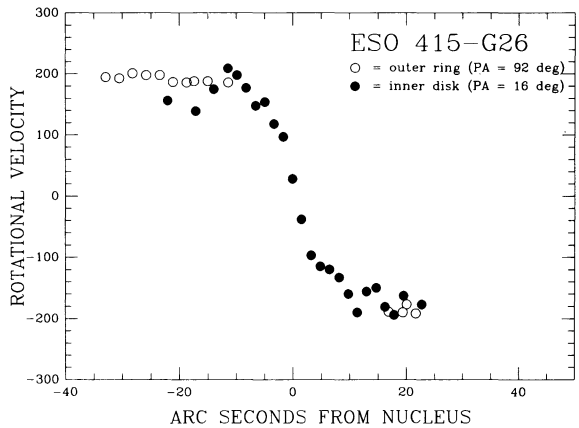

Figure 1 - Rotation curve for both components of ESO415-G26
