Abstract
Purinergic receptors are important for the regulation of inflammation, muscle contraction, neurotransmission and nociception. Extracellular ATP and its metabolites are the main ligands for these receptors. Occasional reports on beneficial results of ATP administration in human and animal studies have suggested the bioavailability of oral ATP supplements. We investigated whether prolonged daily intake of oral ATP is indeed bioavailable. Thirty-two healthy subjects were randomised to receive 0, 250, 1250 or 5000 mg ATP per d for 28 d by means of enteric-coated pellets. In addition, on days 0 and 28, all thirty-two subjects received 5000 mg ATP to determine whether prolonged administration would induce adaptations in the bioavailability of ATP. ATP supplementation for 4 weeks did not lead to changes in blood or plasma ATP concentrations. Of all ATP metabolites, only plasma uric acid levels increased significantly after the administration of 5000 mg of ATP. Prolonged administration of ATP was safe as evidenced from liver and kidney parameters. We conclude that oral administration of ATP only resulted in increased uric acid concentrations. On the basis of these findings, we seriously question the claimed efficacy of oral ATP at dosages even lower than that used in the present study.

Key words: Human studies: Oral ATP administration

Next to its intracellular role as an energy carrier, ATP and its metabolites function extracellularly as the main ligands involved in purinergic signalling. Purinergic signalling is important for the regulation of inflammation, muscle contraction, neurotransmission and nociception (see Bours et al. and Burnstock (1–3) for recent reviews). Modulation of purinergic signalling by administration of purine receptor antagonists (e.g. clopidogrel(4)) or by intravenous administration of ATP or adenosine(5,6) has been shown to effectively modulate human health.

Despite the small number of studies on the effectiveness of oral ATP administration to modulate purinergic signalling, capsules and tablets containing ATP at dosages between 90 and 250 mg/d are being marketed on the Internet as being highly efficacious. Capsules containing 30 mg ATP are presently registered in France (Atépadène®) as an adjunct in the treatment of low back pain of muscular origin. In the late 1980s, two randomised, double-blind, placebo-controlled trials were published in non-indexed medical journals, showing that administration of 90 mg Atépadène® was safe(7,8). In a recent double-blind trial, the efficacy of Atépadène® for 1 month compared with placebo was investigated in patients with low back pain(9), while in an open-label trial, the same drug was tested against the advice to stay active(10). Both trials indicated that oral ATP had a modest benefit on a secondary end point (the use of rescue analgesics) compared with the non-pharmacological treatment. No differences between ATP and placebo groups were found when considering pain or functional status of the patients. The investigators also noted that in the non-blinded trial, the positive effect might largely be explained by the patients’ knowledge of receiving a drug(9,10).

In order to investigate the bioavailability of oral ATP, we previously conducted a study in which an acute oral dose of ATP was administered as an enteric-coated multiparticulate formulation designed to release its contents in the proximal small intestine (further referred to as...
This single dose of ATP pellets did not result in any increase in blood concentrations of ATP or of its metabolites except uric acid. The results remained similar when ATP was administered directly into the duodenum via a naso-duodenal tube. We concluded from this study that a single dose of oral ATP at the given dosage is not effectively taken up. So far, the oral bioavailability of ATP after prolonged administration (as recommended for oral ATP supplements on the Internet) has only been studied in animals. In experimental studies, contrary to expectations, basal plasma ATP levels in animals treated with 5 mg orally administered ATP per kg for 30 d were lower than those in water-treated control animals, suggesting a potential up-regulation of ATP-metabolising enzymes in plasma over the 30 d study. A similar effect was found when oral ATP doses of 1, 5 or 10 mg/kg were given for 20 d. Interestingly, when a single dose of 14C-labelled ATP was administered directly into the lumen of the jejunum of the rats treated with ATP for 30 d, a rapid 1000-fold increase in portal plasma ATP concentration was found compared with the control rats. The authors suggested this to be the result of breakdown of ATP to adenosine by intestinal nucleotidases, followed by increased absorption of adenosine by nucleoside transporters present in the intestinal membrane, in combination with an increased efflux of ATP and nucleosides from intestinal cells into the blood stream. Several nucleoside transporters are now known, belonging to two families of concentrative and equilibrative nucleoside transporters. To test whether such an adaptive metabolic response to chronic ATP administration as observed in animals might also occur in humans, we set out to study this in healthy human volunteers.

The present study had two specific objectives: first, to establish whether whole blood and plasma concentrations of ATP and its degradation products are influenced by oral administration of 0, 250, 1250 or 5000 mg ATP per d for 4 weeks in healthy human subjects; and second, to investigate whether 4 weeks of oral ATP administration leads to adaptations in uptake, metabolism and excretion of a single acute 5000 mg dose of ATP. Adverse events were registered and safety was monitored by measuring a set of liver and kidney blood parameters.

Materials and methods

Study design

A total of thirty-three subjects were assigned in a blinded manner to one of four dosage groups by computer-generated randomisation lists with a block size of eight. On days 1–27, subjects were instructed to ingest enteric-coated pellets twice a day, delivering a daily dose of ATP of either (a) 5000, (b) 1250, (c) 250 or (d) 0 mg (placebo). On days 0 and 28, all the subjects received a single dose of 5000 mg ATP as enteric-coated pellets. Subjects ingested the pellets with approximately 200 ml of water that had been acidified to a pH between 1 and 5.

Participants

Healthy male and female volunteers were recruited. Exclusion criteria were: history of lung, heart, intestinal, stomach or liver disease, use of prescription medication (except contraceptives), smoking, drug use, dietary restrictions and pregnancy. Furthermore, only subjects aged 18–60 years could participate. To minimise between-subject variation, the subjects were requested to abstain from products containing alcohol or caffeine as well as from purine-rich foods, such as game, offal, sardines, anchovies and alcohol-free beer for 2 d before test days 0, 7, 14, 21 and 28. Subjects were asked to fast from 22.00 hours the previous day until the end of test days 0 and 28 (16.00 hours) and to refrain from any vigorous physical activity 24 h before each test day. On days 0 and 28, subjects were allowed to drink water starting 30 min after ATP administration. On all intervening days, the subjects were instructed to ingest the pellets at two self-chosen moments during the day, each one either at least half an hour before or 2 h after a meal. The present study was conducted according to the guidelines laid down in the Declaration of Helsinki, and all procedures involving human subjects were approved by the Ethics Committee of Maastricht University Medical Centre, The Netherlands. A written informed consent was obtained from all the subjects.

Materials

ATP disodium salt and adenosine were purchased from Fagron BV, Uitgeest, The Netherlands. ADP disodium salt, AMP Na salt, adenine, inosine, hypoxanthine, uric acid and perchloric acid 70 % solution in water were purchased from Sigma Chemical Company (St Louis, MO, USA). KOH, KH2PO4, K2CO3, K2HPO4·3H2O and NaOH were obtained from Merck (Darmstadt, Germany) and 0.9 % saline was purchased from Braun (Melsungen, Germany).

Production of pellets

Pellets were obtained from the laboratory of Pharmaceutical Technology, Ghent University, Ghent, Belgium. ATP pellets were produced as described by Huyghebaert et al., with minor modifications to obtain an ATP content of >40 % (w/w) after coating. Placebo pellets were produced in the same manner, but without ATP. The pellets were coated with 30 % Eudragit® L30D-55 (Röhm Pharma, Darmstadt, Germany) and mixed with anionic copolymers of methacrylic acid and ethyl acrylate (1:1). After coating, the pellets were cured overnight at room temperature at 60 % humidity, packed in sealed double-plastic bags and stored at 4 ºC. Pellets were used within 3 months after production. To ensure blinding of all personnel involved in
the study, a separate person not otherwise involved in the study mixed the ATP and placebo pellets at proportions needed to obtain the different doses (0, 250, 1250 and 5000 mg ATP/d), packaged and sealed the pellets in small plastic bags each containing one daily dose and coded them with subjects' identification numbers according to the randomisation list.

**Dissolution testing**

The pellets underwent quality control using a dissolution test as described before^{11}. This test confirmed that the dissolution properties of the pellets were similar to those used in our previous study^{11}. The release of ATP or degradation products after 120 min in 0.1 M-HCl was <3%. Subsequent transfer to a buffer solution of pH 6.5 caused a release of 50% of the remaining ATP within 10 min, which increased to >90% after 60 min (data not shown).

**Sample collection**

On days 0 and 28, subjects arrived at the study facility (Maastricht University Medical Centre) at about 08.00 hours. Venous blood was collected from the antecubital vein using a 20-gauge intravenous catheter (Terumo-Europe NV, Leuven, Belgium) connected to a three-way stopcock (Discofix®, Braun Melsungen AG, Melsungen, Germany). Blood was collected into 4 ml EDTA tubes (Venosafe, Terumo-Europe NV) by inserting a 21-gauge multisample needle (Venoject Quick Fit, Terumo-Europe NV) into the membrane of a closing cone (IN-Stopper; Braun Melsungen AG) that was attached directly to the stopcock. The anticoagulant EDTA inhibits the extracellular hydrolysis of ATP by Ca^{2+}- and Mg^{2+}-activated enzymes, such as plasma membrane-bound CD39^{13}. Serum tubes were used to collect the samples for the assessment of safety parameters (see later for details). After blood collection, the tubes were gently inverted three times and put on ice. For whole blood measurements, 500 μl EDTA blood was immediately added to 500 μl ice-cold perchloric acid (8%, w/v), vortex-mixed and frozen in liquid N_2_. For plasma ATP determination, every second sample of EDTA blood (Venosafe, Terumo-Europe NV) was drawn into a 4 ml EDTA tube (Venosafe, Terumo-Europe NV) by inserting a 21-gauge needle (Venoject Quick Fit, Terumo-Europe NV) into the membrane of a closing cone (IN-Stopper; Braun Melsungen AG) to which was attached a three-way stopcock. The anticoagulant EDTA inhibits the extracellular hydrolysis of ATP by Ca^{2+}- and Mg^{2+}-activated enzymes, such as plasma membrane-bound CD39^{13}. Serum tubes were used to collect the samples for the assessment of safety parameters (see later for details). After blood collection, the tubes were gently inverted three times and put on ice. For whole blood measurements, 500 μl EDTA blood was immediately added to 500 μl ice-cold perchloric acid (8%, w/v), vortex-mixed and frozen in liquid N_2_. For plasma ATP determination, every second sample of EDTA blood was diluted 1:2 with FireZyme Dilution Buffer (Bio/Medica Diagnostics, Inc., Windsor, CA, USA) automatic analyser.

**Uric acid and creatinine measurement in urine samples**

Urine samples were thawed and uric acid and creatinine levels were measured using an automated analyser (Beckman-Coulter, Sharon Hill, PA, USA). Uric acid concentration was corrected for creatinine by dividing the uric acid concentration by the creatinine concentration.

**Safety parameters**

In order to assess the safety of a 4-week period of daily administration of pellets containing up to 5000 mg ATP, concentrations of creatinine, alkaline phosphatase, alanine aminotransferase, lactate dehydrogenase and creatine kinase were measured in undiluted serum samples using a Beckman Synchron CX5 (Beckman Instruments, Inc., Gladesville, CA, USA) automatic analyser.

**Statistical analysis**

Results are reported as means and standard errors. Fasting whole blood ATP and metabolite concentrations were calculated from one sample taken in the morning on days 7, 14 and 21 and from the average of three samples taken at 30, 20 and 10 min before administration on days 0 and 28. The change in area under the curve (ΔAUC) from the fasting concentration on day 0 was calculated using the trapezoidal rule for each subject for the 28-d period. ΔAUC on days 0 and 28 during the 420 min following
ATP administration were calculated relative to baseline values on the same day. For uric acid in urine and for plasma ATP, the AUC was calculated using the trapezoidal rule. Differences in ΔAUC or AUC between dosage groups were evaluated with one-way ANOVA, and a least significant difference post hoc test when appropriate. Differences in response to 5000 mg ATP between days 0 and 28 were evaluated with a paired t test. All the analyses were performed using SPSS 17.0 (SPSS, Inc., Chicago, IL, USA), and P<0.05 was considered statistically significant.

Results

Study population

A total of thirty-two healthy volunteers (thirteen men and nineteen women) completed the 4-week intervention study. Men were on average 28.8 (SEM 1.4) years old and weighed 69.4 (SEM 9.2) kg with a BMI of 21.8 (SEM 1.5) kg/m² while women were on average 21.7 (SEM 4.6) years old and weighed 66.7 (SEM 6.5) kg with a BMI of 22.8 (SEM 1.6) kg/m². One female participant (assigned to the placebo group) dropped out of the study because of repeated vomiting after ingesting the pellets. All other subjects tolerated the daily administration generally well. Temporary nausea without vomiting occurred in two women between 120 and 135 min after ingestion of the first 5000 mg dose of ATP on day 0 of the study. Other minor remarks included a bad taste of the pellets (n=1) and a diminished appetite (one female subject from the highest dosage group).

ATP and metabolites in whole blood

No significant change in fasting whole blood ATP concentration occurred over the entire 4-week intervention period, using doses of 0–5000 mg/d of ATP (Table 1). Administration of a single oral dose of 5000 mg ATP on days 0 and 28 of the study also did not lead to increased ATP concentrations in whole blood during the 420 min following administration in any of the groups, and there was no difference in response to ATP between days 0 and 28 (data not shown). The concentrations of adenosine and other metabolites, except uric acid, were not increased after oral administration (data not shown). Uric acid concentrations increased significantly over the 4-week period, and this was only observed in the 5000 mg dosage group v. the 0, 250 and 1250 mg dosage groups (Table 1). On days 0 and 28, administration of a single dose of 5000 mg ATP increased uric acid concentrations on average up to 40% above fasting concentrations (Fig. 1). Uric acid concentrations started to increase at approximately 30 min after ATP administration, and levelled off at approximately 150 min until at least 300 min after ATP administration. The ΔAUC for uric acid over the 420 min period following administration of the single dose of 5000 mg ATP did not differ significantly between days 0 and 28 nor between dosage groups (Table 2).

Plasma ATP

Fig. 2 shows that plasma ATP concentrations after administration of 5000 mg ATP on days 0 and 28 did not differ significantly between the different dosage groups (P=0.42 for day 0 and P=0.47 for day 28), nor between days 0 and 28 (P>0.05).

Uric acid and creatinine in urine

Analysis of urine samples collected on days 0 and 28 of the study revealed no clear upward or downward trend in uric acid concentrations relative to creatinine (Fig. 3). There was no significant difference between days 0 and 28

within each dosage group ($P>0.10$ for all dosage groups). Within days 0 and 28, there were no differences between the dosages of ATP ($P=0.92$ on day 0 and $P=0.22$ on day 28).

### Safety parameters

As shown in Table 3, none of the safety parameters changed in response to administration of up to 5000 mg ATP for 4 weeks and all median concentrations remained in the reference range for healthy volunteers. Although we observed some individual values for alkaline phosphatase, lactate dehydrogenase and creatine kinase above the reference range, this occurred to a similar extent at baseline (i.e. before ATP/placebo administration) and after 28 d, and also occurred to a similar extent in the placebo and the highest ATP dose group (Table 3).

### Discussion

In this randomised, double-blind, placebo-controlled trial, we investigated the effects of a 4-week period of daily oral ATP administration. The first objective of the present study was to assess whether prolonged daily oral administration of ATP would lead to increased blood and plasma concentrations of ATP and its degradation products. Even after 4 weeks of oral administration, we detected no rise in concentrations of ATP or any of its metabolites, except for uric acid, which showed a significant overall increase in the highest ATP dosage group compared with the other dosage groups over the 4-week period.

Our findings partly agree with previous studies conducted in rats (5 mg/kg per d for 30 d) and rabbits (20 mg/kg per d for 14 d) by Kichenin et al. (12,17), who found no increase in erythrocyte ATP and adenosine concentrations. However, these authors even reported a decrease in basal plasma ATP concentrations in rats receiving 5 mg/kg per d for 30 d (12). High-dose oral ATP administration trials in human subjects have not been reported before. In one previous trial, healthy males ingested much lower doses of ATP (0, 150 or 225 mg/d) for 14 d. No significant increase in ATP levels was observed and no other metabolites were measured in that human trial (18).

It is known that ATP is quickly metabolised in the small intestine. First, ecto-nucleotidase triphosphatase diphosphohydrolases present on the luminal side of enterocytes dephosphorylate ATP via ADP to AMP (19). Secondly, AMP is also not likely to stay intact in the small intestine, since ecto-5' -nucleotidase (CD73) and alkaline phosphatases degrade it to adenosine (20). Adenosine can be transported to the intestinal villi and into erythrocytes by nucleoside transporters.
We suggest that the enzymes adenosine deaminase (present in endothelial cells) and xanthine oxidase (present in the liver) efficiently degraded adenosine to uric acid\(^{(22)}\). This could explain our observation that exclusively uric acid was found to be increased during ATP administration. This increase in uric acid, but not in ATP or other metabolites, upon administration of a single dose of 5000 mg ATP is in accordance with our earlier findings\(^{(11)}\). Uric acid has an elimination half-life of approximately 20 h\(^{(23)}\). Indeed, the uric acid concentration we observed in the present study did not decline much during 6 h after administration of 5000 mg ATP. Since pellets were ingested twice a day from days 1 to 27, the periods between ATP ingestion were close to 12 h; therefore, partial transfer of uric acid from the last dosage from the previous day may have contributed to the

observed rise in basal uric acid concentrations on days 7, 14, 21 and 28 (Table 1). The implications of this increase in uric acid concentration are discussed later.

Our second objective was to investigate whether the uptake, metabolism and excretion of an acute oral ATP bolus would be influenced by prolonged administration (4 weeks) of 250, 1250 or 5000 mg/d of oral ATP. For this purpose, we performed an experiment with a single acute dose of 5000 mg ATP on day 0 and repeated this experiment in all subjects on day 28. Results showed that, again, only the concentrations of uric acid, and not of ATP or any of the other metabolites, increased immediately after the single dose of 5000 mg ATP. Furthermore, there were no significant differences in concentration changes between days 0 and 28 for any of the measured compounds. Although NS, the data presented in Table 2 and Fig. 1(d) suggest that in the highest dosage group (5000 mg ATP), the rise in uric acid concentrations in response to administration of 5000 mg ATP on day 28 was smaller than on day 0. Since we found no increase in uric acid excretion in the urine samples collected on day 28 (Fig. 3), a more efficient excretion of uric acid is not likely to be the cause.

Previous studies in animals showed that, while systemic concentrations did not change, concentrations of ATP and its metabolites in the portal vein increased after prolonged ATP administration. Clearly, in our healthy volunteers, we could not sample portal blood to clarify the intestinal fate of ATP(12).

With the present study, we intended to explore whether oral administration of ATP by enteric-coated pellets could be used as an alternative to other means of ATP administration. Intravenous administration of ATP has been described to elicit marked health benefits and promote survival in cancer patients(5,6,24–31). Although it is feasible to intravenously administer ATP at home, some drawbacks include the increased risk of side effects, difficulty of achieving venous access and the need for medical supervision(5,6,24–31). Previous studies with oral administration of ATP have employed either ATP in solution or relatively large enteric-coated capsules. The latter has the drawback of being difficult to target a specific area of the small intestine due to gastric retention and unreliable enteric coating(18). In the present study, we prevented these problems by using small enteric-coated pellets with a well-defined release profile, which in addition was tested in pilot experiments. Although the pellets were well tolerated and did release their contents, we could not demonstrate any increase in systemic ATP levels in contrast with intravenous ATP administration.

The present results have important implications. First, the reported efficacy of oral ATP supplements that are available through web stores or as registered drugs should be reconsidered. As we find no change in whole blood ATP concentrations at dosages several times exceeding the dosages administered via currently used oral ATP supplements, the present results justify the strong doubts regarding the claims on these supplements as being effective in providing ATP to the body. Secondly, the observed increases in uric acid concentrations in the present study may well explain some of the physiological effects reported after oral ATP administration in previous studies. Uric acid has a controversial reputation: it is at the same time thought to be (1) an important physiological antioxidant that reduces oxidative stress, (2) a normally innocent metabolic waste product that only causes gout or kidney stones if present in excessively high concentrations and (3) a causal factor for hypertension, obesity and vascular and renal diseases(32–35). With regard to the first hypothesis, there are indications that uric acid may have anti-inflammatory activities in conditions such as multiple sclerosis, Parkinson’s disease and acute stroke(36–38). These may be partly due to the strong antioxidant capacity of uric acid. The use of oral ATP-containing supplements to increase uric acid concentrations might be of therapeutic value for these diseases. Secondly, the pro-inflammatory properties of uric acid crystals have long been known to be involved in gout. The uric acid deposits that occur predominantly in joints after prolonged periods of excessively high concentrations of uric acid can eventually trigger an inflammatory response(39). Uric acid is also known to act as a ‘danger signal’, when it is released from necrotic cells(40). Hyperuricaemia is often defined as uric acid >71 mg/l (420 µmol/l) in men and >61 mg/l (360 µmol/l) in women(41,42). In the present study, the blood concentrations of uric acid stayed below these values. Our data on creatinine, alkaline phosphatase, alanine aminotransferase, lactate dehydrogenase and creatine kinase also demonstrate that daily administration of 5000 mg ATP is safe. As for the third hypothesis, given the complex relationship of uric acid with other established cardiovascular risk factors, such as obesity, the metabolic syndrome, diabetes and especially hypertension, and due to the lack of prospective studies, it remains unclear whether uric acid is indeed a causal factor for these conditions(43,44). In conclusion, the present study shows that a 4-week period of daily administration of ATP as enteric-coated pellets does not lead to increased plasma or blood ATP concentrations, nor is there any evidence of a metabolic adaptation in the uptake or metabolism of ATP. The present results cast serious doubt on the health claims of oral ATP supplements.
