Abstract. One of the remaining open issues in the context of the analysis of Active Galactic Nuclei (AGN) is the evidence that nuclear gravitational accretion is often accompanied by a concurrent starburst activity. We developed a spectral energy distribution (SED) fitting technique to derive simultaneously the physical properties of active galaxies and coexisting starbursts making the best use of \textit{Spitzer} and \textit{Herschel} IR observations. We apply the SED fitting procedure to a large sample of extragalactic sources representing the HerMES (\textit{Herschel}/Multi-tiered Extragalactic Survey) population with IRS spectra with a plethora of multi-wavelength data in order to study the impact of a possible presence of an AGN on the host galaxy’s properties. We analyze the star formation rate (SFR) in connection to the presence of an AGN and compared the properties of the hot (AGN) and cold (starburst) dust component. Our findings are consistent with no evidence for the presence of an AGN affecting the star formation processes of the host galaxies.

Keywords. galaxies: active – galaxies: starburst – galaxies: star formation – infrared: galaxies

1. Introduction

Intense episodes of star formation extend up to kpc scale, while in the inner tens pc of active galaxies we find, according with the unified model of AGN (Antonucci et al., 1985; Urry et al., 1995), a toroidal dusty structure surrounding the central super massive black hole. There is a lot of evidence for an intimate link between the two mechanisms both from the theoretical and observational side. Among the most important: i) the need to introduce AGN feedback to quench star formation in cosmological simulations and semi-analiticals models (e.g. Bower et al., 2006; Croton et al., 2006); ii) the correlation between the mass of the SMBH and that of the bulge of the host galaxy (e.g. Ferrarese & Merritt, 2000); iii) AGN and starbursts have been found to coexist in galaxies at all redshifts (e.g. Alexander et al., 2005).

The main issue here is to understand whether a causal relationship exists between star formation and nuclear gravitational activity. Quantifying the relative importance between the two was, till recently, extremely difficult, as they both happen in dusty environment producing thus a lot of IR photons. It is exactly the IR where the efforts to investigate these two coeval phenomena should be concentrated. With data coming from \textit{Spitzer} and \textit{Herschel} we are now able to built the IR SED of extragalactic sources up to 500 \textmu m. In particular, in the work presented here we use \textit{Herschel}-SPIRE (250, 350 and 500 \textmu m)
data coming from the HerMES (Herschel Multitiered Extragalactic Survey, Oliver et al., 2012) survey. These along with Spitzer-IRAC and -MIPS photometry allow us to cover both the peaks of the AGN (mid-IR) and starburst (far-IR) emissions. Moreover, the mid-IR spectra from the Spitzer-IRS spectrograph provide information about the emission and the absorption of the silicate features associated with the silicate grains in the dusty torus. PAH (Policyclic Aromatic Hydrocarbons) molecules in star-forming regions also manifest themselves with spectral features between 6 and 13 μm. In this context the information coming from the IRS spectra plays a crucial role and the simultaneous use of Spitzer and Herschel data provide extensive information on the manner in which the two phenomena coexist.

2. Sample Description and SED fitting tool

Our sample comprises 375 sources with flux greater than 3σ at 250 μm, with σ comprising both the instrumental noise and the confusion limit (Roseboom et al., 2010) in four of the northern HerMES fields, namely Boothes HerMES, FLS, Lockman Swire and ELAIS N1 SWIRE. All the sources of our sample had a reliable estimates of redshift (either from an optical or IRS spectrum) and IRS spectrum available from the Cornell Atlas of Spitzer/Infrared Sepctrograph Project (CASSIS, Lebouteiller et al., 2011).

To investigate simultaneously the properties of the AGN and starburst we applied a fully automatic multi-component SED fitting technique able to reproduce the optical/UV-to-FIR SED of galaxies. Three components of emissions are considered: i) a sum of simple stellar population models (SSP) having solar metallicity from Bertelli et al. (1994) to account for the stellar optical-UV emission, a revised grid of the Fritz et al. (2006) AGN torus models (presented in Feltre et al., 2012) for the bulk of the mid-IR emission and empirical classical starburst templates to reproduce the emission at longer wavelengths. Photometric data and IRS spectra are fitted simultaneously with the methodology described in Feltre et al. (2013) in order to have more constraints on the models. In a second step, we fitted the photometric points at λ > 100 μm with a modified black body (with the dust emissivity index kept fixed, β = 2, and the temperature allowed to vary) in order to have an estimation of the temperature and the mass of the cold dust.
3. Results and Discussion

We use a threshold value of the equivalent width of the PAH (measured on the IRS spectra), $\text{EW}_{\text{PAH}}$, equal to 0.2 (as found by Hernán-Caballero & Hatziminaoglou, 2011) to separate mid-IR AGN- ($\text{EW}_{\text{PAH}} < 0.2$) and starburst- ($\text{EW}_{\text{PAH}} > 0.2$) dominated objects. We use the PAH feature at 11.3 $\mu$m and that at 6.2 $\mu$m when the first was not available. Mid-IR AGN-dominated objects are further divided in obscured and unobscured, on the basis of the presence or no of the stellar component in the total best-fitting model.

We compare various physical properties:

- $\text{SFR}_{\text{FIR}}$, which is the SFR obtained applying the Kennicutt et al. (1998) prescription, $\text{SFR}_{\text{FIR}}=4.5\times10^{-44} \text{L}_{\text{SB}}$, where $\text{L}_{\text{SB}}$ (in erg/s) is the luminosity of the best fit starburst galaxy templates integrated between 8-1000 $\mu$m;
- $\text{L}_{\text{acc}}$ is the accretion luminosity of the best-fitting AGN torus models, representing the emission coming from the central accretion disk of AGN;
- $\text{SFR}_{\text{PAH}}$, which is the SFR obtained using the correlations of Hernán-Caballero et al. (2009), $\text{SFR}_{\text{PAH}} = 1.4\times10^{-8} \text{L}_{\text{PAH}[6.2]}$ and $\text{SFR}_{\text{PAH}} = 1.52\times10^{-8} \text{L}_{\text{PAH}[11.3]}$ where $\text{L}_{\text{PAH}[6.2]}$ and $\text{L}_{\text{PAH}[11.3]}$ are the luminosities of the PAH features 6.2 and 11.3 $\mu$m, respectively;
- the mass of the hot dust correspondent to the best-fitting torus model;
- the mass and the temperature of the cold dust estimated fitting the FIR data with a modified black body.

In Fig. 3 we report some of the main results of this work, extensively discussed Feltre et al. (2013). $\text{SFR}_{\text{FIR}}$ correlates with $\text{SFR}_{\text{PAH}}$ (left panel) as already found by previous authors (e.g. Schweitzer et al., 2006; Netzer et al. 2007; Lutz et al., 2008). Starburst-dominated objects (red stars) show the tighter and steeper correlation, very close to the 1:1 relation (dashed black line). The reason why $\text{SFR}_{\text{FIR}}$ takes higher values with increasing SFR can be sought in the fact that the ratio between $\text{L}_{\text{PAH}}$ and $\text{L}_{\text{SB}}$ depends on this last. Indeed, we find a decrease of $\text{L}_{\text{PAH}}/\text{L}_{\text{SB}}$ with increasing $\text{L}_{\text{SB}}$. To investigate whether the presence of an AGN could affect the obscured SFR we compared the $\text{SFR}_{\text{FIR}}$ as function of $\text{L}_{\text{acc}}$ (right panel of Fig. 3) finding the first increasing with the AGN luminosity. Moreover, we find the ratio between $\text{L}_{\text{SB}}$ and $\text{L}_{\text{acc}}$ to decrease with $\text{L}_{\text{acc}}$.

Finally, we compared the properties of the hot (AGN heated) and cold (starburst heated) dust component. When fitting the modified black body we consider only objects with Spitzer-MIPS 160 $\mu$m in order to sample both sides of the cold dust emission peak. The mass of the hot dust and the cold dust mass do not show any evidence of a correlation (see left panel of Fig. 3). This reflects the fact that the two mechanisms occupy very different physical scales and, moreover, that gravitational effects that drive the star formation do not divert a fixed fraction of the gas towards the AGN centre while...
the starburst is ongoing. As can be seen in the right panel of Fig. 3 we also do not find any dependence of the temperature of the cold dust on $L_{\text{acc}}$.

To summarize, our findings do not provide evidence that the presence of an AGN can affect significantly the star formation processes of the host galaxies but rather than the two phenomena occur simultaneously over a wide range of luminosities. This is consistent with the expectation to see an average effect when considering large IR sample. Indeed, most models predict a very brief feedback phase, implying that a correlation between hot and cold dust properties is not expected to be seen, even with a feedback itself being very strong.
