SPECTRAL ENERGY DISTRIBUTION AND INTERSTELLAR REDDENING (Review Paper)

L. HOUZIAUX and J. MANFROID Institut d'Astrophysique,4200 Cointe-Ougrée, Belgium

Abstract. - We review the recent results on flux distribution of Be stars from 320 to 850nm. It appears that data are available for only 10 to 15 % of the objects recognized as "normal" Be stars. The main current problems appear to be the variability of the continuous radiation, and the correction for interstellar reddening. Various attempts to solve these matters are discussed. We stress the need for fairly high (lnm) resolution spectral scans obtained simultaneously with data in other spectral ranges, repeated at appropriate intervals of time. Such requirements make it necessary to restrict the observing programmes to a limited sample of carefully chosen objects.

Although emission lines have been recognized in B-type spectra already in 1866, it took more than 50 years to realize that such objects might have also spectral energy distribution different from non-emission-line stars of nearby spectral types. Partial reviews on the subject are somewhat scattered over the literature, but a clear and thorough account will be found in Doazan (Underhill and Doazan, 1982).

Early work on Be stars continuous spectra has been done either photographic spectrophotometry (Greaves and Martin, 1938; Barbier and Chalonge, 1941) and also by observers of early-type stars in the UBV by photometric system. The UBV system is, for obvious reasons, not well suited for flux distribution studies, but it is useful for detecting brightness variations. The reddening is most of the time characterized by a E(B-V) color excess.

There are two specific areas which deserve careful work in this respect:

- the first one is the collection of highly accurate calibrated data on intrinsic Be star fluxes over the whole wavelength range; this implies that we are able to correct the spectral observations for the effects of interstellar obscuration;

- the second is the problem of light variability, which implies repeated measurements over appropriate time scales.

This means that obtaining accurate energy distributions from the satellite ultraviolet to the microwave region even for a limited number of objects is a rather formidable task and that, with regard to such a goal the present situation is all but satisfactory. Nevertheless, considerable progress has been accomplished in the recent years, especially in the infrared, which is the subject of a separate review for this colloquium, and will thus not been reported on here. So we shall be mainly concerned here with the visible region and with the ultraviolet inasmuch it has to do with interstellar reddening effects.

The current situation is summarized in Table 1, giving the main sources of information on continuous energy distribution of Be stars (see the detailed reference table at the end of the report). Noting that the recent Catalogue of Stellar Groups(Jaschek and Egret, 1982) contains 1260 bona fide Be stars with an MK type, this means that we have spectrometric observations for roughly 10% of this restricted sample in the visible and in the infrared, and that the situation is somewhat better in the ultraviolet.

Results of the new observations in the 13-color system (Johnson and Mitchell, 1975) have been published by Alvarez, Schuster, and Guichard (Alvarez and Schuster, 1981, 1982; Schuster and Alvarez, 1983; Schuster, 1984; Schuster and Guichard, 1984). The 13 color (13C) system is based on filters of intermediate bandwidths, covering the 337 to 1100 nm range. 8 color indices are used to characterize the stars photometrically and, although the system is very sensitive to reddening, it permits to construct unreddened indices (Mendoza et al, 1983).

According to the authors such data serve to determine "intrinsic colors, reddening values, approximate MK spectral types, surface gravities,

distances. angular and linear diameters for normal B stars", and, "with only a few assumptions", most of these procedures can be extended to Be stars. In his paper where he establishes the calibration of the 13C system , Schuster (1984) explains how to derive intrinsic color excesses for Be stars. His method is based primarily on the idea that a Be star may be assigned a non emission B MK type, for which intrinsic colors are known from standard stars photometry. Second, he assumes that the 400nm-450nm color excess is entirely due to an interstellar absorption whose properties are isotropic and invariable with distance. Hence, the observed colors of the Be star are dereddened according to this scheme. The remaining differences between the standard MK-type colors and the dereddened Be stars colors give the "intrinsic" color excesses. It is shown that way that an extra Balmer edge absorption is observed for 48 Lib, while for Chi Oph, it appears in emission, while both stars have a marked color excess in the red. These results are well-known from other types of spectrometries. However, in the 13C system all indices are such that they are close to zero for an average main sequence AO star, and are not really calibrated in terms of flux ratios. Hence, it is difficult to translate the color indices into physical quantities. For instance, the Balmer jump is evaluated by the 330nm-630nm index, and requires correction for reddening. On the other hand, the sample of comparison stars is rather limited (20 objects) in the spectral range where most Be stars are found. A standard star may show up to 0.2 magnitude in E(B-V)excess, which amounts to a large absorption in the ultraviolet. Schuster and Guichard (1984) give 8 and 6 color photometry of 89 Be and shell stars, among which 22 show light and/or color variations. The variations range from possibly variable objects (0.05 mag.) to very variable objects (0.15m) in the 580 nm band.

Luminosity and colour variations of 88 Her in the 155-550nm range have been studied by Barylak and Doazan (1986). During the period 1972-1983, the star has passed from a quasi-normal B phase to a Be phase. Doazan, Thomas and Barylak (1986) propose to associate the luminosity drop at the onset of the Be phase with an increase of mass outflow and a photospheric temperature drop of about 1000 °K. The strengthening of the shell spectrum, associated with an increase of luminosity reflects either an increase in photospheric radius or a mild increase in photospheric temperature but no change in photospheric radius.

In the frame of a general, statistical approach to the problem of B star variability, Waelkens and Rufener (1983) have indicated how important it is to start from a large and unbiased sample. From measurements made in the Geneva color system, these authors build up parameters which are strictly photometric and which permit to separate the various types of variables, and in particular, the Be stars.

A general study of the Be variability has been made by Kogure (1984), who characterizes the three relationships between emission line intensities and the V magnitude as parallel, mutually independent, and antiparallel. Photometric and spectroscopic behaviour of Pleione and EW Lac indicate a correlation between an increase of the U-B excess and a higher optical depth in H alpha. This phenomenon may be due to an

increase of electron density in the envelope.

Since the pioneering work of Mendoza (1958), it is known that Be stars, classified in the MK system show in the U-B, B-V plane a large scatter around the reddening vector. Recent work in the UBV system brought up interesting new results concerning the light and color variabilities namely :

- the discovery of the eclipsing binary nature of zeta Tau (Pavlovski and Bozic, 1982);

- the strictly periodic variations of 4 Be stars (over 7) in the cluster NGC 3766 (Balona and Engelbrecht, 1986). The amplitudes are of a few percent in B, with periods of the order of one day. The authors find that the observations are best represented by a spotted rotator model;

- The same type of explanation is proposed by Harmanec (1984, a, b) for rapid variations of 3 Be stars.

- let us also mention studies in UBV by Hopf et al (1982, Pleione), Bartoloni et al (1982), Pavlovski (1983), Fernandes (1984) and Balona (1985). A list of stars with periods around one or two days has been published by Percy (1982).

Harmanec and his collaborators organized an international campaign of Be stars watch. Many observers (and among these Z.H. Guo, L. Huang, V.M. Lyuti, J.R. Percy, A.S. Sharov, C. Stagg and J. Ziznowsky) joigned the team and reports are regularly issued in the Be star Newsletter, edited by M. Jaschek.

The Walraven VBLUW system has been used by van Leeuwen et al (1982) to study Pleione.

HD 172256 has shown in the Strömgren uvby system a period shorter than one day (Heck et al, 1984). In this system, several Be stars have been included in a survey program of "Long Term Photometry of Variables", currently under development at ESO (Sterken, 1984). D. Baade is the coordinator for the Be star group.

Narrow band systems allow to isolate lines and compare continuum and line emission or absorption (H-alpha, HeI 5876) Mendoza et al (1983), measured hot stars (04-B8) in their system called lambda (9), alpha (16). (For details, see Mendoza 1975, 1976, 1979 a, b, 1981). The alpha (16) index allows to single out stars with emission at H-alpha. Be and shell stars are clearly separated from non-emission B stars in the alpha (16), lambda (9) plane. Mendoza et al (1983) also find a correlation between the alpha (16) index and the mass loss rate.

Guinan and Hayes (1984) succeeded in watching photometrically a major mass loss onset in omega Ori at the H-alpha wavelength. Large variations have also been seen in the continuum at 435 and 658.5 nm. A preliminary study using interference filters has been started by Cester et al (1982) on Be stars.

Various papers by Goraya (1984, 1985 a, b, c; Goraya and

Singh, 1984; Goraya and Joshi, 1982), based on 50 A resolution scans, indicate that early Be stars (BO-B5)show more frequently color excess in the near UV and near infrared than do later sub-types. Some Be stars have an effective temperature lower than normal B stars (Goraya, 1985), but other Be's are in this respect very similar to non-emission B stars (Goraya and Singh, 1984). The infrared color excess is a common feature of Be stars. Goraya also finds a correlation between the infrared excess and the intensity of the Balmer jump in emission.

Such a conclusion on the temperature of Be stars is also reached by Zorec et al (1983). They use data from the BCD classification scheme and ultraviolet monochromatic magnitudes from the S2/68 experiment.

They introduce an ultraviolet reddening free index G = m(146) - m(274) - K m(146) - m(235), K being the appropriate ratio of color excesses, for which they find a relatively high value (-11.21), using the average interstellar reddening law of Savage and Mathis (1979). This high value is due to a relatively small value of the color excess E(146nm - 235nm). The scatter in the diagram spectral type-G index is then fairly high, especially for representative points of emission line stars, relatively to the average curve representing BIV-BV stars. This is not too surprising when one realizes the variety of individual reddening curves. Furthermore the G index computed from Kurucz models is in serious disagreement with the values obtained from observations, especially for supergiants.

Their conclusion is that around 235nm most Be stars would have more fluxes either higher and sometime lower than B stars and that these differences simultaneously with strong emission characteristics (strong low Balmer lines, high Paschen lines emission, infrared excess). They suggest that the Be stars be classified into 2 categories according to their emission strength. They also find no correlation between their ultraviolet color index and V sin i.

Such a method is perhaps not entirely free from interference of circumstellar material. Schild (1983) has shown that among 7 Be stars, four stars may show color excesses due to absorption by circumstellar matter, producing no 220nm-bump in the ultraviolet. This is an alternate explanation to the large value of the E(B-V) excess as due to supplementary emission in the V band.

An attempt has been made also by Zorec and Briot (1985) for establishing the part of the E(B-V) color excess due to interstellar reddening. They first try to solve the problem starting from normal B stars, where usual procedures of the UBV system and the Paris BCD classification parameters lead to a classical value of E(B-V) for non emission stars. Results of the method levelling off the 220nm depression as described by Beeckmans and Hubert Delplace (1980) are shown to lead to values somewhat smaller than for non-emission stars.

An alternate method makes use of fitting the 220nm feature

with a Lorentz profile(Gutler et al, 1982) which leads to values consistent with the previous one (as corrected by Zorec and Briot).

Surrounding stars then provide a new method based on a relationship between the color excess and distance in the direction close $(2^{\circ} \text{ to } 5^{\circ})$ to the direction of the star studied. Hence, this method requires the knowledge of the absolute magnitude of the star. It is then applied to 55 Be stars and the authors recognize that their application is not just as straight forward as in the case of non-emission stars, due to a poor knowledge of absolute magnitude (they do not seem to consider Be stars in clusters) and to variations in V. Assuming a non variability of the absolute magnitude of the Be stars, they deduce a V magnitude of the Be stars as it were outside a shell phase. This V magnitude serves to compute the distance, using the absolute magnitude of a B star of the same spectral type of the Be star.

There are of course several sources of uncertainties in the determination of E(B-V) by such a procedure. It seems that the method using surrounding stars leads to smaller E(B-V) values that the 220nm absorption bump. This might be an indication of a possible contribution of circumstellar matter to the Be flux depression around 220nm, a result in some way in contradiction with Schild's findings that circumstellar matter would contribute to E(B-V) and not to the 220nm bump.

This means that the matter of flux comparison between B and Be stars in the 215-235nm region is far from being settled. Let us note that Divan and Zorec (1982) applied to 59 Cygni a method based on a gradient discrepancy between the stars (observed during a non-emission-phase) and an unreddened object of similar BCD spectral type. This method led to values in good agreement with E(B-V) values obtained from UV fluxes.

A more physical attempt to obtain the true interstellar + circumstellar part of the color excess E(B-V) has been recently made by D. Kaiser (1984). In his doctoral thesis, he develops a method of finding the fundamental characteristics of the underlying photosphere of a Be star. The main assumption in this work is the fact that a Be star may be modellized by a system made of a normal B star, plus a temporary shell, responsible for the photometric variations and optically thin in the near infrared region.

Observations consist of high quality scans of 26 bright Be stars from 320 to 880nm (Kaiser, 1986). The sample has recently been extended to 16 other stars by Hanuschik (1986). The main idea is to determine a set of values of E(B-V) interstellar, Teff and log g from fitting interpolated model fluxes to the observed flux distribution in the widest possible range. A basic procedure developed for 3 standard nonemission stars leads to results in good agreement with other determinations. This makes use of a fitting also of the Balmer jump.

The situation is of course less favourable for Be stars since the two discontinuities already observed in the BCD spectra also appear, restricting the wavelength range to 370 to 880nm. At this point, another difficulty appears, namely that even that for this spectral region, no set of parameters E(B-V), Teff and log g will lead to a satisfactory agreement, because of the well-known infrared radiation excess. The fluxes being normalised at 550nm, it is clear that the difference between the observed fluxes and the model fluxes at wavelengths longer than 556nm are only minimal values.

Theoretical considerations on energy distribution emitted by a thin envelope lead Kaiser to determine the amount by which the 556nm magnitude has to be corrected to account for the shell contribution. Hence a new flux for the stellar photosphere is determined and a new and final determination of the Be star photosphere may be determined, as well as an interstellar E(B-V) value. Results indicate rather low values of interstellar E(B-V) but most of the observed stars are bright and relatively close.

These objects have also been observed in the ultraviolet. Taking into account the correction proposed by Kaiser at 556nm, it is possible to compare the observed fluxes by S2/68 (Jamar et al, 1976), IUE (Heck, 1984) or OAO-2 (Code et al, 1980) with fluxes derived from the Kurucz model parameters proposed by Kaiser for the same star. In general, observed fluxes are somewhat (0.2 to 0.4 magnitude) lower than the fluxes expected from the models. Such a discrepancy may be interpreted in terms of a too high temperature scale, or in terms of a complementary source of opacity in the stellar or circumstellar atmosphere.

In conclusion, we may say that much remains to be done to have a satisfactory knowledge of Be type star flux distributions in the visible wavelength range. In order to separate the effects of interstellar and intrinsic reddening, it is advisable to have accurate and well resolved (lnm) energy distribution over a range 320 to 900nm. It is clear that these observations have to be carried out simultaneously over all practicable wavelength ranges. Because of normalisation problems, it would be advisable to have absolute fluxes at one wavelength. Furthermore because of variability problems, it is necessary to repeat at appropriate intervals of time the observations and hence to concentrate on a restricted observing list of objects. DISCUSSION FOLLOWING HOUZIAUX

Doazan:

I would like to recall that our analysis of the luminosity changes of 88 Her, from the far UV to the visual, through phase changes (quasi-normal B to Be shell) has shown that the occurrence of a shell spectrum is *preceded* by a luminosity drop in all the observable wavelengths, indicating a decrease in photospheric temperature of about 1000 K. There is no far UV excess nor deficiency relative to a normal Be star's radiative energy distribution. Such a change indicates that the thermodynamic state of the photosphere is linked to the formation of a shell, i.e. an enhancement of the mass outflow from the star.

Peters:

When one observes a B star in the visual spectral region, one is observing but a few percent of the total flux from the star. We have been obtaining continuum data on selected Be stars with the *Voyager* spacecraft, which are capable of recording 40-70% of the flux of such a B star. Tomorrow we will present evidence from *Voyager* data that the surface temperature of α Eri varies by 750 K. This value is consistent with the run of values (except for one extreme one) given in your table.

Houziaux:

It may well be indeed that the effective temperatures obtained by various authors at different times reflect variations of temperatures of Be stars as you demonstrated in the case of α Eri. This proves, however, that although a small amount of the total energy is concentrated in the range 320-850 nm, this range is sufficient to obtain an accurate value of $T_{\rm eff}$. On the other hand the correction for interstellar reddening is much safer in this range than in the far ultraviolet. From what you are saying, it seems that in the future, it will be necessary to assign to a Be star not only a value of $T_{\rm eff}$ but also a range of variation in $T_{\rm eff}$. Such variations may reflect the release of matter opaque to continuum radiation affecting also the photospheric radius.

Snow:

I have comments on the determination of interstellar extinction. First, I was interested to learn that there is statistical evidence of enhanced 2200 Å absorption in Be stars. I think it's far more likely that this is due to extra line absorption than to circumstellar extinction, because there is an extensive literature showing no evidence for circumstellar dust in Be stars and no circumstellar 2200 Å absorption, even in stars with dust. Also, I think the use of diffuse interstellar band strengths to indicate interstellar extinction ought to be more widely applied. The diffuse bands correlate well with E(B-V) and apparently are never formed in circumstellar material. Furthermore, with modern detectors the relatively narrow bands in the red can be accurately measured even in stars with E(B-V) as small as 0.10. This method of finding E(B-V) avoids problems with using clusters or nearby stars to estimate reddening.

Houziaux:

I agree inasmuch it is proven that these relationships of diffuse features versus E(B-V) are isotropic.
