Glucocorticoids are vital hormones that are released in response to stress to regulate a number of physiological functions, including metabolism, inflammation and cardiovascular activity. Their release is characterized by an ultradian (pulsatile) pattern of hormone secretion which disturbance has been linked to obesity(1). The literature provides evidences suggesting that fasting can affect glucocorticoid secretion both by increasing hormone synthesis in the adrenal and by increasing corticosterone half-life(2). This project was aimed to further elucidate the mechanisms underlying the observed changes in corticosterone secretion.

An automated blood sampling system was used to collect blood samples over a period of 24hrs from rats that were allocated to one of the three experimental groups: ad libitum, fasted and fed group. The blood plasma was further analysed by a radioimmune corticosterone assay to quantify the corticosterone levels. By using a reverse transcriptase quantitative polymerase chain reaction the gene expression in the adrenal gland was measured from rats subjected to the three experimental conditions.

This study has established that, compared to ad libitum fed animals, fasting increases, while feeding decreases, basal corticosterone levels (Figure 1A), but neither conditions affect the hormone response to a mild stressor. Moreover, the increased corticosterone secretion in fasted rats was paralleled by a decrease of the inhibitory protein DAX-1 (Figure 1B), that is known to be crucial for the expression of key steroidogenic genes in the adrenal. A change of only one steroidogenic factor suggests a more complex adrenal response to fasting, possibly involving other metabolites acting on the gland.
