#### Introduction

People report that face masks can cause communication difficulties. We investigated aspects of speech processing which might cause these difficulties.

Face masks create a visual barrier.

Visual cues from the speaker's face and mouth can improve speech intelligibility significantly, even when the image is imperfect (e.g. due to distance in classrooms).

Face masks cause acoustic changes.

For example, masks can reduce the overall intensity and cause changes to high frequencies. However, there is limited evidence that these acoustic changes affect speech recognition accuracy. Mild processing cost may be captured more effectively measuring reaction times (RT) instead of accuracy.

Semantic sentence predictions are vital to processing connected speech.

This is especially important when the signal is distorted. High predictability could reduce visual and auditory processing difficulties caused by face masks.

Children are less experienced in using semantic cues for predictive speech processing.

A concern might be that children cannot use semantic cues as effectively as adults to compensate for adverse listening conditions. Mask research has so far concentrated on adults.

# Research Questions

- . Does listening to speech through face masks increase mental effort, affecting processing speed (RT)?
- 2. What are the relative contributions from visual blocking vs. acoustic changes?
- Can linguistic context (semantic predictability) make up for (acoustic) bottom-up processing difficulties?
- 4. Do the three effects (visual, acoustic, predictability) affect children in the same way as adults?

### Methods & Materials

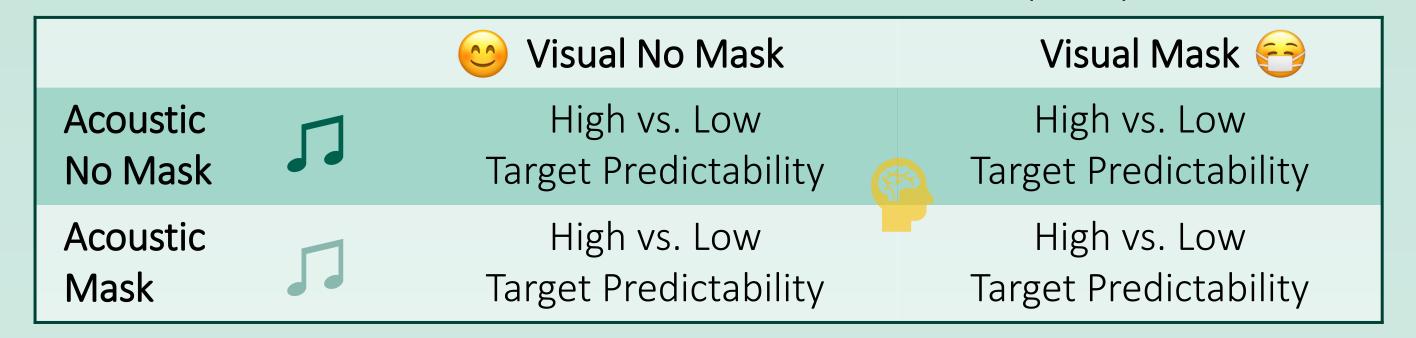

Participants (preliminary subsample)

16 British English (BE) adults (age 20-60), 16 BE children (age 8-12)

#### Materials

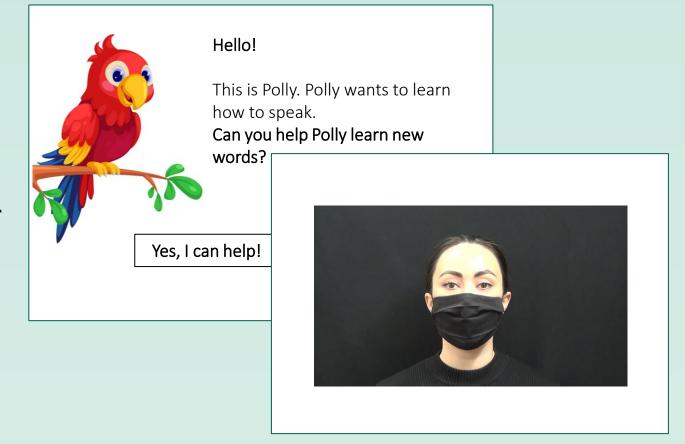

120 target words embedded in sentence-final position, manipulated by Visual Mask Effect x Acoustic Mask Effect x Semantic Predictability of the target word (cloze probability)

For your birthday I baked this cake. (High) Examples: Tom wants to know about this cake. (Low)

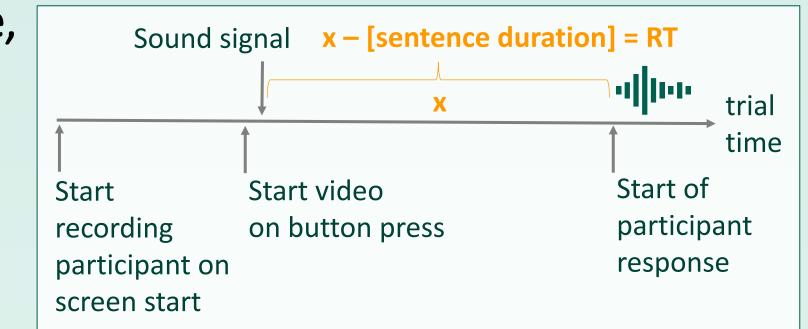

#### Procedure

- Experiment conducted online on Gorilla experiment builder
- Participants watched videos of a BE speaker and repeated the last word of the sentence that they heard (cued shadowing).

# Analysis

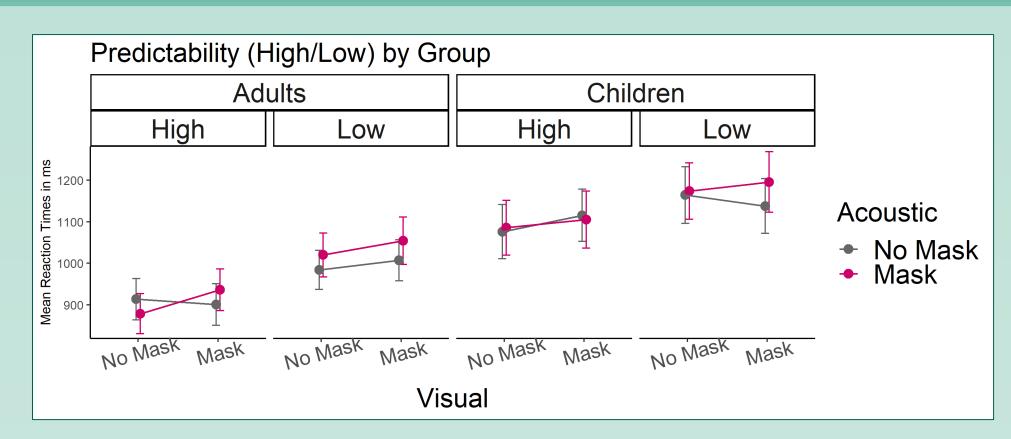

- A sound signal at the beginning of each sentence serves as an anchor for calculating reaction times.
- With this new technique, cued shadowing can be conducted online with high precision and accuracy, with children and adults.

- Participant responses are marked with the help of automatic speech onset recognition (Chronset) and manual corrections.
- Reaction times are statistically analysed with mixed effects modelling with four main effects (visual cues, acoustic cues, predictability, age group) and respective two-way interactions.

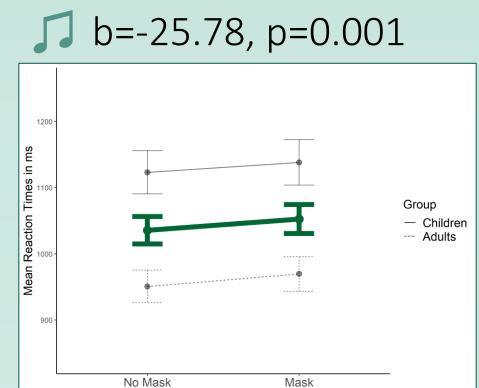

# Results (preliminary subsample)

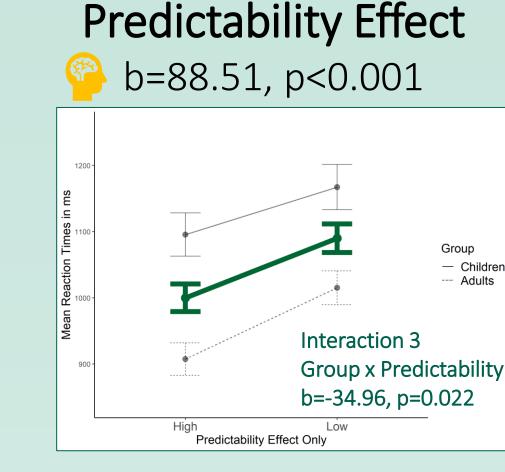

#### Overview of All Effects

#### **Individual Main Effects**

# **Acoustic Mask Effect** Visual Mask Effect \$\footnote{1} b=-31.32, p<0.001

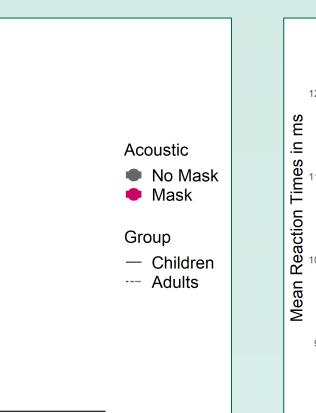

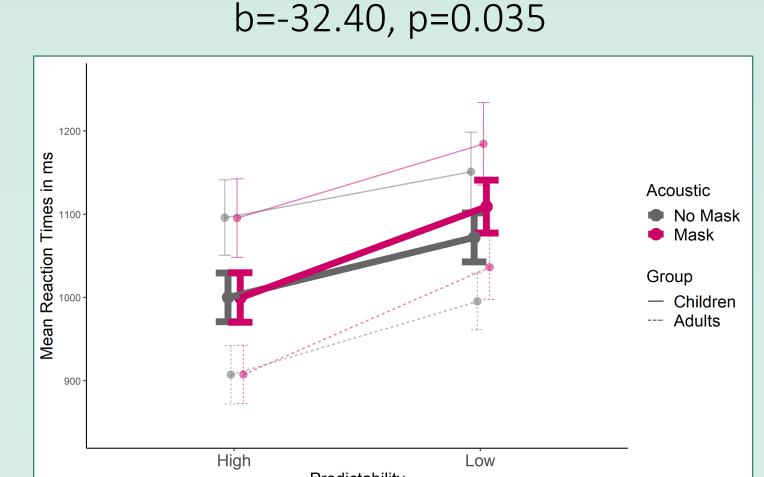

## Interaction 1

#### Visual x Acoustic Mask Interaction b=33.89, p=0.029

# Acoustic x Predictability Interaction

Interaction 2

- Listening to speech through face masks slows down processing, leading to longer response latencies.
- 2. Visual and acoustic mask effects individually are very small (10ms), but interestingly show a larger effect in combination (40ms) when one modality cannot compensate for the other.
- 3. High semantic predictability reduces these mask effects significantly overall, and largely makes up for acoustic processing difficulties.
- 4. Children are less proficient in predictive processing, but use semantic cues to compensate for mask effects in a similar fashion to adults.
