

A Review of Ancillary Tests in Evaluating Brain Death

Manraj K. S. Heran, Navraj S. Heran, Sam D. Shemie

ABSTRACT: The neurological determination of death (NDD) is primarily considered to be clinical. However, situations may arise where confounding factors make this clinical assessment difficult or impossible. As a result, ancillary tests have been developed in order to aid in the confirmation of brain death. As assessment of neuronal electrical activity; electroencephalography (EEG) is no longer recommended in this determination, tools assessing cerebral perfusion, as reflected by the presence or absence of cerebral blood flow (CBF), are the mainstay of NDD. The preferred ancillary test currently is Hexamethylpropylene amine oxime-single photon emission computed tomography (HMPAO SPECT) radionuclide angiography. When this is not available, or is equivocal, 4-vessel cerebral angiography can be used to determine the presence or absence of intracranial blood flow. However, as cerebral angiography has its own limitations, other techniques are sought by physicians in the Intensive Care and Neuro-intensive Care settings to replace cerebral angiography. In this article, we briefly review the history of diagnosis of brain death, pathophysiologic issues in making this determination, and currently available CBF imaging techniques, discussing each in turn with respect to their utility in the diagnosis of brain death.

RÉSUMÉ: Analyse des tests d'appoint dans l'évaluation de la mort cérébrale. La détermination neurologique de la mort (DNM) est considérée comme étant basée principalement sur la clinique. Cependant, il existe des situations où des facteurs confondants rendent cette évaluation clinique difficile, voir même impossible. Des tests d'appoint ont donc été mis au point afin de faciliter ce diagnostic. L'évaluation de l'activité électrique neuronale (ÉEG) n'est plus recommandée. Les outils permettant d'évaluer la perfusion cérébrale, soit la présence ou l'absence de flux sanguin cérébral (FSC), sont devenus les tests de choix pour déterminer la DNM. L'épreuve d'appoint de choix actuellement est l'angiographie isotopique (SPECT HMPAO). Quand cet examen n'est pas disponible ou que ses résultats sont équivoques, une angiographie cérébrale des 4 vaisseaux peut être utilisée pour déterminer la présence ou l'absence de FSC. Cependant, l'angiographie cérébrale a ses propres limites et les médecins oeuvrant à l'unité de soins intensifs ou de soins intensifs neurologiques ont recours à d'autres techniques pour y suppléer. Nous analysons brièvement l'historique du diagnostic de mort cérébrale, les aspects physiopathologiques de la DNM et les techniques d'imagerie qui sont disponibles pour l'évaluation du FSC. Nous discutons de l'utilité de chacune de ces techniques pour établir un diagnostic de mort cérébrale.

Can. J. Neurol. Sci. 2008; 35: 409-419

Brain death. The very concept has stirred much debate for decades. Referred to as “coma depasse” (beyond coma) by Mollaret and Goulon in 1959,¹ the first formalized definition of brain death was by the Ad Hoc Committee of the Harvard Medical School in 1968.² Since then there has been a greater understanding of neuronal function and mechanisms of brain cell injury,^{3,4} with the emergence of a concept of “death of the person rather than the body”, as described by Bonetti et al.⁵ Brain death is now considered as complete and irreversible loss of brain function,⁵⁻¹⁰ or as the Canadian Neurocritical Care Group defined it in 1999, “the irreversible loss of the capacity for consciousness combined with the irreversible loss of all brainstem functions including the capacity to breathe”.¹¹

Articles, such as those by Baron et al¹² and Bernat,¹³ nicely review the concept of brain death, as well as discuss continuing

areas of controversy, such as whole-brain death versus death of the brain stem. As modern medicine can now allow survival of an individual in situations once considered hopeless, knowing the evolution of the concept of brain death is important in order to keep perspective on the person, rather than the body.

METHODS

A literature review based on a MEDLINE search of relevant articles between January 1966 and October 2006 was conducted. Keywords included the following: brain death, neurological determination of death, computed tomography (CT), magnetic resonance imaging (MRI), perfusion, xenon, transcranial Doppler, radionuclide, cerebral blood flow, angiography, stroke, ischemia, and infarction. Search parameters were combined to find articles relevant to the discussion of perfusion and/or angiographic imaging in the evaluation of brain death.

Principles of Cerebral Perfusion

The cerebral circulation refers to the blood vessels in the brain, both arterial and venous. Cerebral blood flow (CBF) refers to the amount of blood that enters the brain over a period of time, and is a specific parameter describing cerebral perfusion. The human brain uses approximately 20% of the cardiac output. CBF is tightly regulated to meet the brain's metabolic demands, and on average must be maintained at a flow of 50 milliliters of blood per 100 grams of brain tissue per minute (50mL/100gm/min).¹⁴⁻¹⁹ With reduction in CBF, there is proportionately increasing oxygen extraction from delivered blood. Furthermore, in brain starving for oxygen, at a threshold of greater than 50% reduction in CBF, or close to the level of CBF reduction associated with clinical changes, there is an increase in lactate production from anaerobic metabolism.^{20,21} Complete suppression of protein synthesis appears to occur below CBF values of 35 mL/100g/min. Glucose utilization transiently increases between flow rates of 25-35 mL/100g/min, with a precipitous decline below this range. Below 25 mL/100g/min, tissue acidosis becomes more pronounced as anaerobic glycolysis dominates, and intracellular phosphocreatine and ATP also decline.¹⁶ The CBF must drop to less than 20 mL/100gm/min to get ischemic neuronal activity reduction and reversible neuronal changes.²² This is when a person typically becomes clinically symptomatic of their ischemic neurovascular condition. Experimental studies in cats²³ and primates,²⁴ and clinical studies performed during carotid endarterectomy surgery in humans²⁵ have shown loss of spontaneous and evoked electrical activity when CBF values fall below 16-18 mL/100g/minute. Cerebral blood flow values less than 10mL/100gm/min result in irreversible ischemic neuronal damage within minutes, as reflected by membrane failure.^{14-17,26} The CBF values between 10-20 mL/100gm/min are deemed the "ischemic penumbra", and represent neuronal tissue which may potentially be salvaged, if flow restoration occurs before irreversible damage sets in. On the other hand, CBF in excess of 50mL/100g/min is termed hyperemia and can contribute to an increase in intracranial pressure (ICP) which can secondarily lead to ischemia.²¹

Cerebral blood flow is determined by a number of factors, including blood viscosity, blood vessel caliber, and cerebral perfusion pressure (CPP). The CPP is the net pressure of blood

flowing into the brain and is determined by subtracting the ICP from the systemic mean arterial blood pressure (MAP).²⁷ Cerebral blood vessels are able to self-regulate CBF through autoregulation,²⁷ a process in which blood vessels constrict when systemic blood pressure is raised and dilate when blood pressure is lowered.²⁸ When pressures are outside the range of 60 to 150 mmHg, the blood vessels' ability to autoregulate pressure through dilation and constriction is lost, and cerebral perfusion is determined by blood pressure alone, a situation called pressure-passive flow.²⁸ Similar loss of autoregulatory ability can also be seen in injured brain, potentially leading to sudden increase or decrease in the total intracranial intravascular blood volume, and even leakage into the brain due to blood-brain barrier dysfunction. In sudden or extreme situations, this may contribute to ICP variation affecting cerebral blood flow. Arterioles also constrict and dilate in response to different metabolite concentrations in the local environment.²⁸ For example, they dilate in response to higher levels of carbon dioxide and H⁺ in the blood. Although the Lund protocol allows for CPP to be as low as 50 mmHg in adults and 40 mmHg in children for short periods of time, it is widely accepted that CPP in an adult human cannot go below 60-70 mmHg for a sustained period of time without causing ischemic brain injury.^{27,29,30}

The Role of Ancillary Tests

Brain death is a clinical diagnosis. As such, many authors have previously outlined the clinical criteria for brain death.^{13,31,32} Important aspects of the clinical examination in brain death, such as apnea testing, have recently been reviewed.³⁰ However, many confounding factors may exist (Table 1). Though the clinical diagnosis of brain death may be difficult in young children and neonates, ancillary testing is not

Table 1: Confounding factors in the clinical diagnosis of brain death

-
- 1.) In situations in which clinical criteria cannot be reliably applied
 - a. Cranial nerves cannot be adequately examined
 - i. Trauma to eyes
 - ii. Trauma to middle and/or inner ears
 - iii. Cranial neuropathies
 - b. Neuromuscular paralysis
 - i. Neuropathies
 - ii. Drug-induced

 - d. Heavy sedation
 - e. When apnea test not valid (such as in high carbon dioxide retainers)
 - f. Profound metabolic and endocrine disturbances that are difficult to reverse
 - 2.) In young children
-

routinely recommended in this setting due to confounding factors on CBF assessment. Shemie et al discuss such issues in young children and neonates.³¹ However, in the older child and adult, features of the clinical exam may not be able to be safely implemented. It may not be possible for a patient to undergo an apnea test. Patients with eye injuries may not be amenable to appropriate assessment of pupillary, corneal, or vestibulo-reflex testing. Those with perforated tympanic membranes will not be able to undergo ice water caloric testing for vestibulo-ocular reflexes. As a result, although confirmatory testing of cerebral blood flow is not mandatory in North America in the clinical diagnosis of brain death, there has been much interest in ancillary tests for aiding in the diagnosis of brain death when specific components of the clinical examination cannot be reliably performed.^{8,31} Indeed, in certain European, Central and South American, and Asian countries, legislation requires ancillary tests as part of the diagnostic criteria for establishing brain death.^{32,34}

The Ideal Ancillary Test

The ideal ancillary test must fulfill several criteria (Table 2). There must be no false positives (ie, no cerebral blood flow, yet the individual survives), and very few false negatives.¹³ In addition, testing that could be done at the bedside would be best, as this would avoid transferring potentially hemodynamically unstable patients from the Intensive Care Unit (ICU).³⁵ Currently, there is no ideal ancillary test. The objective of ancillary testing is to determine the point of cessation of cerebral arterial circulation.³⁶⁻³⁸ Through considered application of ancillary tests, cases where the clinical diagnosis of brain death is confounded can be assessed. Earlier determination of brain death may then allow for avoidance of protracted stays in the ICU, and potentially expedite organ donation before tissue viability becomes a concern.

Types of Ancillary Testing in Brain Death

There are several types of ancillary tests currently available that can assess cerebral perfusion and its effects on the brain

parenchyma. These tests differ on the basis of availability, reproducibility, reliability, and sensitivity. Whereas certain tests such as radionuclide angiography are relatively easy to administer, other examinations, such as four-vessel cerebral angiography, require transportation of the patient to specialized areas of the hospital outside the ICU and involve subspecialty expertise in order to perform and analyze the examinations. The decision to use one ancillary test over another is therefore dependent on many factors, including safety of the patient, sensitivity and specificity of the examination, and availability of the ancillary test. Existing literature regarding the use of some of these tests in the setting of brain death can be found in Appendix A, while Appendix B provides a comparative overview of existing tests assessing cerebral perfusion. In short, though several of the ancillary tests currently available meet many of the criteria outlined in Table 2, none are ideal.

Examinations Assessing Brain Structural Changes

Computed Tomography

Computed tomography is a powerful modality for evaluating neurologic disorders. It is readily available, rapidly performed, and does not necessarily require subspecialty expertise to interpret. In the setting of brain death, the classical non-contrast CT head (NCCT) findings have been well described.³⁹ These include: diffuse cerebral edema, loss of differentiation between the gray and white matter structures globally, and herniation patterns resulting from the cerebral edema. Dominguez-Roldan et al⁴⁰ concluded that two signs on NCCT were significantly associated with brain death. These were midline shift of greater than 10 mm, and compression of the ambient cistern. Geraghty and Torbey⁴¹ conducted a study assessing the prognosis of patients becoming comatose after cardiac arrest. In their article, they describe the use of a gray matter-to-white matter Hounsfield attenuation ratio (GM:WM) to predict brain death, with a cutoff of 1.18. Using this cutoff, 100% of those patients with GM:WM ratios of <1.18 died, whereas 54% of those above this cutoff survived. However, despite the ability of NCCT to depict changes reflecting parenchymal injury, it is not sensitive or specific enough to be used as an ancillary test for determination of brain death as, in many cases, there is no midline shift and the GM:WM ratios may initially not be significantly abnormal, even though brain death has occurred.

The concept of using an intravenous contrast-enhanced CT head examination (CECT) in the assessment for brain death is not new.⁴²⁻⁴⁴ Tan et al⁴⁴ directly compared cerebral angiography with dynamic NCCT and CECT examinations in five patients clinically confirmed as brain dead. They found that the intracranial circulatory arrest associated with brain death in these patients resulted in no contrast opacification intracranially, whereas normal circulation was present in the scalp (supplied by external carotid artery branches). Dupas et al⁴³ also demonstrated stagnation and arrest of contrast flow at the level of the internal carotid and vertebral arteries on their two-phase helical CT examinations. However, they also confirmed that the superior sagittal sinus could be seen in up to 50% of their study population, presumably opacifying via meningeal artery perfusion or trans-diploic emissary veins draining the scalp tissues to the superior sagittal sinus. The internal cerebral veins,

*absence of intracranial blood flow refers to no visualization of the vertebrobasilar circulation or the anterior circulation above the level of the carotid siphons in those clinically determined to be brain dead; **all assessments were done with clinical brain death as the primary inclusion criterion; ^in infants and children older than one month; n/a – none available

vein of Galen, and straight sinus were never opacified in their study.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has revolutionized neuroimaging and its use in evaluating virtually every type of neuropathological state is beyond debate. Much like in CT, the classical findings on MRI in clinically confirmed brain death include brain swelling, various herniation patterns, obliteration of the cerebrospinal fluid (CSF) spaces, and compression of the ventricular system.^{32,45,46} The ratio of signal intensity between the gray and white matter has been noted to increase after the clinical diagnosis of brain death^{45,46} and serial examinations performed in a patient proceeding on to clinical brain death have demonstrated these temporal changes in progressive brain failure.⁴⁷ As MRI is superior to CT in the evaluation of flowing blood, this feature has been examined as well. Jones and Barnes⁴⁸ confirmed absent CBF on flow-sensitive gradient-echo

sequences. This lack of intracranial arterial flow voids has also been documented by others.^{32,46,49} Diffusion-weighted imaging (DWI) may also be a potentially useful tool in the assessment of brain death. McKinney et al⁵⁰ nicely reviewed the histopathologic correlation of brain tissue infarction with DWI findings and Kumada et al found a significant drop in the apparent diffusion coefficient (ADC) values of the involved parenchyma in those with a clinical diagnosis of brain death,⁵¹ also shown by Nakahara et al.⁵² It is suggested that the white matter may demonstrate greater ADC reduction following brain death than the gray matter.^{52,53} However, DWI lacks the sensitivity and specificity necessary to accurately predict global brain function on the basis of regional DWI changes.

Magnetic resonance spectroscopy (MRS) has also been applied in the evaluation of brain death.^{38,47,54-56} The MRS findings have been variable, with no characteristic pattern typical of brain death. Though certain derangements of metabolites, such as the production of lactate, would be expected as neuronal

Appendix B: Comparison of Ancillary Tests for Determination of Cerebral Blood Flow in the Setting of Brain Death

Test	Definition	Minimum Flow Limit (mL/100g/min)	Advantages	Disadvantages	Consensus
<i>DSA</i>	Digital subtraction angiography	0	Direct visualization of CBF	Invasive Exposure to iodinated contrast Not readily available Not portable, Expensive	Reference standard for NDD assessment Not preferred test due to invasiveness
<i>SPECT</i>	Single photon emission computed tomography	5	Widely available Portable, Low cost Whole brain coverage	Not quantitative Poor spatial resolution	Reference standard for NDD assessment
<i>PET</i>	Positron emission tomography	0	Quantitative, Can assess multiple factors, including oxygen consumption, by using different radioligands Repeated measurements possible, Whole brain coverage	Impractical for everyday use Expensive Not portable	Reference standard for CBF assessment Not useful in NDD
<i>XeCT</i>	Xenon computed tomography	0	Quantitative Allows simultaneous CT-based imaging techniques Can be repeated within 10 minutes	Only available in a few academic centers as not FDA approved, Not portable, Limited brain coverage (6 cm), Delivery of Xenon gas may present challenges	Reference standard for CBF assessment Not useful in NDD due to limited availability
<i>MRA</i>	Magnetic resonance angiography	Dependent on technique of acquisition, but considered very low (<10)	Readily available No contrast necessary Can be combined with other MR-based techniques	Not readily available, Expensive Not portable, Scanning time lengthy	Limited data but promising
<i>MRP</i>	Magnetic resonance perfusion	8	Readily available Whole brain coverage Can be combined with other MR-based techniques Repeatable	Not quantitative for CBF Not readily available Not portable	Likely not useful as not quantitative
<i>CTA</i>	Computed tomography angiography	Unknown but likely very low (<10)	Readily available Rapid acquisition	Exposure to iodinated contrast Not portable	Limited data but most promising as ubiquitous technology
<i>CTP</i>	Computed tomography perfusion	0	Readily available Rapid acquisition Rapid acquisition Quantitative*	Exposure to iodinated contrast and ionizing radiation Limited anatomic coverage (2-4 cm), Requires post-processing of data, Relies on intact BBB, Not portable	Limited data but holds promise, especially if anatomic coverage extended
<i>TCD</i>	Transcranial Doppler Ultrasound	Unknown	Rapid Non-invasive Portable	Does not quantify CBF Difficult to perform, One measurement for each, hemisphere	Not deemed useful in NDD

* controversy exists regarding its true quantitative abilities

death occurs,³⁸ these changes become clearly abnormal fairly late after the clinical diagnosis of brain death,³⁸ or may not always be visible on MRS.⁴⁷ Non-proton MRS, such as sodium or phosphorus-based techniques, may be potentially more powerful in the assessment of brain death, as they may allow imaging of the ATP-dependent pathways or neuronal membrane integrity.⁵⁴ However, the practical application of these techniques has not yet been validated. Therefore, much like routine CT, conventional MRI, even with DWI and MRS, lacks the sensitivity and specificity to be useful as an ancillary test in the evaluation of brain death.

Ancillary Tests for Cerebral Perfusion

The other category of ancillary testing revolves around the general concept that brain tissue not receiving blood flow will eventually suffer irreversible damage, leading ultimately to brain (and brainstem) death. This dependence on cerebral perfusion suggests that tools able to accurately assess the presence or absence of CBF would be helpful in the determination of brain death, as would those tests able to demonstrate neuronal viability. However, whereas the absence of CBF is considered to be an accurate marker of brain death, a person may be brain dead despite the presence of CBF.

Table 3: Angiographic findings in brain death

No visualization of anterior circulation beyond level of supraclinoid ICAs
No posterior circulation filling beyond dural penetration of vertebral arteries
Absence of internal cerebral vein filling

ICA=internal carotid arteries

There are two patterns of brain death which may occur, as proposed by Palmer and Bader.³⁵ One pattern is manifested by an elevation of intracranial pressure (ICP) to a point exceeding the mean arterial pressure (MAP). As a result, no net CBF is present, eventually leading to permanent cytotoxic injury of the intracranial neuronal tissue. It would then follow that tests relying on demonstrating the presence or absence of CBF could be used to determine brain death in this particular pattern.

The other pattern Palmer and Bader describe is one where the ICP does not exceed the MAP, with maintenance of cerebral perfusion pressure to values where CBF should be sufficient to provide the brain with the necessary oxygen, glucose, and other nutrients to allow its survival. In this pattern, there is an intrinsic pathology affecting the brain's neurons on a cellular level which, if widespread and sustained, can also result in brain death. Such a pattern of brain death would be best assessed by a tool able to determine neuronal function/viability. As CBF would be present in this pattern, tests relying on its absence for determination of brain death would be falsely negative in this setting.

It is important to note that one of the major reasons for the markedly elevated ICP is diffuse intracranial parenchymal swelling. Though the ICP must exceed the MAP for no cerebral perfusion to be present, this swelling is not an indefinite phenomenon. Gradually, the swelling will subside and, if the patient is able to still maintain a reasonable MAP, CBF may eventually return. The clinical diagnosis of brain death would still be made in this setting, and tests for neuronal viability/function would also be able to accurately determine this. However, tests relying on CBF could again be falsely negative, suggesting that there may be a time-sensitive nature to the examinations using CBF as a marker of brain death.

There may also be situations where an elevation in ICP resulting in cessation of CBF may not be present. This may occur as a primary phenomenon, as in the case of catastrophic brainstem or cerebellar pathology.^{13,57} Alternatively, this may occur when the rise in ICP has been compensated for or alleviated in some manner. This is a common phenomenon in infants who, because of their open fontanelles and soft, deformable skulls, may show only an attendant increase in their head circumference as a result of situations which would typically cause a markedly raised ICP in those patients with a "closed" cranial vault. Post-traumatic skull fractures may also allow decompression of raised ICP.⁵⁸ Surgical procedures, such

as decompressive craniectomies⁵⁹ and placement of ventricular drains,⁶⁰⁻⁶² are deliberately done to lower the ICP. As a result of these situations, CBF may be maintained, despite non-viability of the brain itself.

In summary, though the sustained absence of CBF will eventually lead to brain death, situations where CBF can be maintained despite documented brain death exist⁶³⁻⁶⁵ (de Campo 1993; Flowers et al 2000; Kurtek et al 2000). It is important to understand the situations in which these false negative results may arise in order to assess the results in context and consider other options for confirmation of brain death.

Tests for Determining CBF

Cerebral Angiography

Among the techniques for determining CBF, cerebral angiography is classically considered to be the reference standard for imaging brain death. Experience in this setting dates back to a landmark paper published by Heiskanen in 1964,⁶⁶ with numerous authors since contributing to the body of knowledge regarding four-vessel cerebral angiography as an ancillary test in the determination of brain death.^{37,38,43,67-69} It is relatively simple to perform, can be done within 30-60 minutes, and is relatively straight-forward to interpret. Though early cerebral angiography examinations for brain death were actually done using iodinated contrast injections in the aortic arch, the currently accepted method of assessment is done with separate contrast injections performed in both common or internal carotid arteries, as well as in both vertebral arteries. Classical angiographic findings in brain death are summarized in Table 3, and include the lack of contrast opacification of the internal carotid arteries beyond the carotid siphon, and filling of the vertebral arteries to, but not beyond, their dural penetration.

Despite cerebral angiography being considered the "gold standard" for determination of CBF, there are many concerns with its use.³¹ Cerebral angiography requires specialized neuroradiologic expertise to perform and interpret the procedure. It is an invasive test, requiring the placement of a catheter into the arterial circulation, with injections performed in the cerebrovascular arterial system. Although the risk of procedural complications is low, the potential exists for vessel damage anywhere along the course of the catheter. As well, the patient must be transported to the Radiology Department for the procedure, with the attendant risks this may bring. Its availability is not always immediate, and the cost associated with this examination is not low. Although no false positive cases have been reported, false negative examinations may occur if cerebral angiography is performed on a patient in whom there is no significant elevation of the ICP,³⁷ or if angiography is performed in a manner where contrast is injected too vigorously into the downstream circulation, thereby artifactually opacifying the intracranial vasculature.^{7,38} Controversy also exists regarding the potential for iodinated contrast to damage transplantable tissues, such as the kidneys.³⁸ As such, though cerebral angiography is a reliable and accurate examination, other options are preferred.

Radionuclide Angiography

In many ways, radionuclide angiography is the ideal ancillary test in the determination of brain death.^{7,31,32,38,48,65,70-72} It is safe,

noninvasive, and portable. It is reliable and reproducible, and is in total agreement with cerebral angiography.⁷³ When combined with HMPAO SPECT, it has been validated for use in the setting of brain death evaluation.^{74,75} Several good articles review the technique for performing HMPAO SPECT radionuclide angiography as well as expected findings in the setting of brain death.^{70,76} Briefly, there should be no intracranial flow on the dynamic phase of imaging, with no uptake of radionuclide within the brain tissue on planar and SPECT imaging. This is referred to as the “empty skull” sign. Because of the maintained external carotid artery perfusion, the nasal region can be quite prominent. This is referred to as the “hot nose” sign. Variable visualization of the superior sagittal sinus may occur,^{38,63} due to flow in the meningeal arteries and/or drainage of scalp venous blood via transosseous emissary veins. If focal residual brain perfusion is seen, this is interpreted as not confirmatory of brain death and a repeat HMPAO SPECT study is typically performed in 24-48 hours. This residual activity may be seen in two fairly distinct distributions, as described by Facco et al.⁷¹ Perfusion may be seen in isolated hemispheric structures, such as the thalami or basal ganglia. This is usually seen in children or in adults with skull defects. Persistent perfusion may also be seen selectively in the posterior fossa structures, reflecting a rostrocaudal deterioration of intracranial tissues.

CT Angiography and CT Perfusion

A natural extension of CT imaging techniques is the application of CT angiography (CTA) and CT perfusion (CTP) for the evaluation of brain death.^{8,32,77-79} Both techniques are readily available on modern multi-detector helical CT scanners, and are simple to implement into practice. According to Widjicks,⁹ CT angiography is well accepted in all European countries, and several non-European countries, as an ancillary test for brain death. It is easily performed, rapidly acquired, requires only an intravenous access, and is not affected by confounding medical factors. The findings are similar to those already described for dynamic CECT in that no intracranial arterial contrast opacification should be seen in the setting of brain death, typically defined as the vertebrobasilar circulation intradurally, as well as above the level of the supraclinoid internal carotid arteries. There is expected visualization of the external carotid arterial system. Leclerc et al⁷⁷ further refine the diagnostic criteria as lack of visualization of the cortical middle cerebral artery branches, as well as lack of visualization of the internal cerebral veins. Despite its lack of portability, CTA is still highly efficacious⁸ and does not have the procedural risks associated with conventional digital subtraction angiography. However, as iodinated contrast is still required to perform this examination, the potential risk of contrast-mediated tissue injury is still present.

Computed tomography perfusion is a technique already in widespread use for acute stroke imaging. Interestingly, the earliest description of a perfusion-type CT scan was actually done over two decades ago.⁴² In comparison to CTA, which is relatively simple to interpret, CTP requires post-processing of the acquired data in order to generate the mean transit time, CBF and cerebral blood volume maps needed to appropriately assess the intracranial parenchyma. As such, this interpretation is typically done by a neuroradiologist, although, in some

institutions, stroke neurologists are also familiar with this technique. Some authors tout CTP as a quantitative tool for measuring CBF.⁸⁰⁻⁸³ This remains an area of debate,²² having yet to be proven in large prospective studies. In the setting of global brain injury, the commonly performed semi-quantitative application of CTP would potentially be a major issue due to its reliance on ratio comparisons to a contralateral “normal” parenchyma. In addition, no technique has yet been developed which allows whole brain coverage through existing CTP techniques, although another level of perfusion imaging can be performed after waiting approximately three-six minutes. Though one may infer that the arterial input function waveform should be flat, there is no actual literature reporting brain death findings on CTP, and its use in the diagnosis of brain death has never been evaluated in a formal fashion.

Xenon CT

Xenon CT (XeCT) is a powerful tool, and has been applied to ischemic cerebrovascular disease for many decades. It provides a quantitative measurement of CBF,⁸⁴⁻⁸⁶ and is also noninvasive, fairly rapidly performed, and provides the added benefit of routine CT imaging of the brain as well. Xenon CT has a high spatial resolution, and flow assessment of the entire brain can be sampled accurately with the three levels of examination typically used. Also, by using inhalational Xenon, an inert gas having CT attenuation characteristics similar to iodine, XeCT avoids the use of iodinated contrast, thereby eliminating issues raised regarding contrast-mediated tissue injury (such as contrast-induced nephrotoxicity).

Many authors describe the use of XeCT in brain death.^{7,32,38,87-89} Thompson et al⁸⁹ compared XeCT to dynamic brain scintigraphy in clinically brain dead children, and determined that negligible (defined as < 5 ml/100 g/minute) or no CBF globally were the CBF parameters required in order to confirm the clinical diagnosis of brain death. Pistoia et al⁸⁸ confirmed these values in 30 patients they studied over seven years.

Though the practical application of the technique is not difficult, its accessibility is a tremendous challenge, as Xenon CT is virtually unavailable apart from at a select number of academic institutions in North America. Again, the patient must be transported to the Radiology Department, and dedicated Neuroradiology expertise is required to perform and interpret the exam. As such, though XeCT remains an immensely powerful tool for quantitative examination of CBF, too many issues exist to allow its ubiquitous use as an ancillary test for the confirmation of brain death.

Magnetic Resonance Angiography and Perfusion

As has already been described, conventional MRI performed in the setting of clinically confirmed brain death can demonstrate the lack of normal intracranial arterial flow voids. This is thought to be a consequence of ICP being greater than MAP, thereby resulting in no net intracranial arterial blood flow. Dedicated magnetic resonance angiography (MRA) has been performed to evaluate this finding.^{32,36,49,90} All assessments thus far have utilized a “time-of-flight” (TOF) or “moving blood” imaging technique, without administration of intravenous contrast. Similar findings as those reported on CTA assessment have also

been reported for TOF-MRA, namely absence of visualization of the vertebro-basilar system intracranially and the internal carotid arteries above the level of the carotid siphons.⁴⁶ External carotid arterial visualization can be seen, as can partial visualization of the superior sagittal sinus for the reasons described earlier. The study by Karantanas et al,³⁶ clearly demonstrated continued visualization of the intracranial arterial circulation in 10 patients who had suffered severe closed head injuries and who did not meet clinical criteria for brain death, as opposed to total lack of visualization of intracranial blood flow in the 20 patients who were clinically thought to be brain dead prior to MR examination. All 10 patients survived, with variable neurologic outcomes. All of the 20 patients having no evidence of MRA-documented intracranial blood flow died.

Controversies exist around the use of MRA for brain death evaluation. Though there are several reports of its use in this setting, no formal evaluations have been done. Because contrast-enhanced MRA is not prone to some of the pitfalls of TOF imaging, such as slow flow, in-plane flow, and non-laminar flow, there has been a progressive shift towards its use in the evaluation of cerebrovascular disorders. However, no reports currently exist in the literature on its use in the neurological determination of death. Although MRA is noninvasive, it still requires the transfer of the patient to the MR scanner. Subspecialty neuroradiologic expertise is again required to perform and interpret the examination. The exam takes longer than CTA, is more prone to technique-related image degradation, and requires MR compatibility of all devices attached to the patient.

Thus, though MRA holds promise, especially when combined with MRI, MRS, and DWI, it has not as of yet been validated for use as an ancillary test for confirmation of brain death.³¹

The MR perfusion (MRP) is a powerful technique, utilizing first-pass magnetic susceptibility effects of administered contrast agents to obtain data similar to CTP.⁹¹ Its main advantage are its greater coverage of the brain during perfusion imaging (whole brain imaging versus 2-4 cm for CTP), as well as the ability to obtain diffusion weighted imaging. However, though the technique can determine CBF to a lower limit of 8 mL/100g/min, MRP is semi-quantitative, and no data is available on its use in the setting of brain death.

Transcranial Duplex Ultrasonography

The utility of transcranial duplex ultrasonography (TCD) as a test for evaluating the presence of intracranial blood flow has been reviewed elsewhere.^{32,38,92} Classical findings in a patient who is brain dead are short systolic spikes or peaks, oscillating movement of blood within the assessed arteries, and disappearance of systolic flow on subsequent testing when previously documented as present. Transcranial duplex ultrasonography has many potential advantages. It is safe, portable, noninvasive, and relatively rapidly performed. As well, it is relatively inexpensive, and does not require administration of potentially organotoxic contrast agents. However, TCD is not widely available, and is quite labour-intensive, requiring tremendous skill and rigor in its application to insonate all of the major intracranial arteries.^{31,32,38} In addition, up to 20% of patients may fail TCD scanning as their cranial vaults are too thick to allow appropriate visualization of these arteries.³² As

well, many authors have reported false positives and negatives using TCD.^{61,93-95} Because of these drawbacks, as well as its lack of validation, TCD is not considered an accurate and reliable ancillary test in the confirmation of brain death.

The Future

Recognizing that false negatives may occur when an ancillary test evaluating the presence or absence of CBF is used, techniques assessing for CBF still appear to be the most promising with respect to a reliable and reproducible diagnosis of brain death in the face of confounding clinical factors. Though CTA has not been accepted for use in North America, its use as an alternative in Europe, and other non-European countries suggests that greater effort be taken to validate it as an ancillary test. Computed tomography perfusion in combination with CTA may be even better; however, no large series of patients have yet been reported and controversy remains regarding its ability to truly quantify CBF. Current advances in MR angiographic techniques in the imaging of cerebrovascular pathology include the use of intravenous contrast agents,⁹⁶ quantitative phase contrast techniques,⁹⁷⁻⁹⁹ and time-resolved MRA.^{100,101} In addition, MR perfusion techniques such as arterial spin labelling may contribute to improved characterization of presence or absence of intracranial blood flow. All of these methods may provide a greater certainty of the presence or absence of CBF, thereby ensuring no false positive exams. However, providing accurate and meaningful CBF data regarding the brainstem remains a challenge. In the future, truly quantitative CT- or MR-based perfusion techniques may be developed, thereby allowing CBF assessment as currently only provided by XeCT or PET. In addition, issues regarding the lack of portability of these different modalities are being addressed, as portable CT scanning units are already commercially available, some with Xenon-CT perfusion capability. Other tests incorporating complementary modalities may also be developed.

CONCLUSION

The diagnosis of brain death remains primarily a clinical determination. However, it is important to recognize that confounding factors do exist that may make clinical diagnosis extremely difficult or impossible. Ancillary tests are then useful in helping make this diagnosis. Tests imaging CBF are the preferred ancillary tests, with HMPAO SPECT radionuclide angiography considered the first-line study. When this is not available or is equivocal, 4-vessel cerebral angiography is another validated examination which can be performed to determine the presence or absence of CBF. Though several case reports exist describing the use of other noninvasive angiographic or perfusion techniques, such as CTA and MRA, currently none of these techniques have been validated for use as ancillary tests in the determination of brain death. Because of the many potential advantages these noninvasive techniques may offer, further efforts should be made to evaluate them as replacement tests for conventional 4-vessel cerebral angiography.
